POPULATION STRUCTURE OF PACIFIC YELLOWFIN TUNA

by

Z. Suzuki,¹ P. K. Tomlinson² and M. Honma³

ABSTRACT

The population structure and production of Pacific yellowfin tuna, *Thunnus albacares*, were examined by studying most of the basic data available on stock assessment, as well as other data, for the period 1965 to 1972. The data were obtained mainly from the Japanese longline fishery in the Pacific Ocean east of about 120°E and from the purse-seine fishery in the eastern Pacific east of about 140°W. Data from genetic studies of subpopulations were not used due to their preliminary nature.

The examination of data on gonad maturity and distribution of larvae indicated three relatively discrete areas of intensive spawning activity along the equatorial zone, i.e. the western, central and eastern Pacific. It was found that the sexual maturation of female yellowfin caught by longline differs from that of those caught by purse seine, and an attempt was made to explain the difference on the basis of the thermal structure of the ocean.

Neither catch-per-unit-of-effort nor length data from the two fisheries showed any appreciable east-west discontinuity although it appears that in most months longline catches between about 110°W and 120°W are not as great as elsewhere. Long-term trends for longline catch rates in various major fishing grounds of the western Pacific were generally similar. On the basis of a brief examination of their vertical distribution it appears that the principal habitat of yellowfin is in the mixed layer. Also, the relation between longline fishing grounds for yellowfin and physical oceanic conditions was briefly examined.

Progressive east-west changes in size at capture were indicated by length-frequency samples taken from yellowfin caught by longline and, to a lesser degree, by purse seine. In order to analyze the meaning of this phenomenon, the extent of migration of this species was reviewed. This examination included data on the occurrence of fish contaminated by radioactivity during the testing of atomic explosives. It was decided that the extent of migration was greater than that estimated by Royce (1964), but probably not so extensive as to result in substantial intermingling among yellowfin tuna of the western, central and eastern Pacific areas. The cline evident in the length data from the longline fishery in the central and eastern Pacific was considered to be an artifact caused by differential size selectivity of the fishing gear in relation to the thermocline topography (Suda and Schaefer, 1965). Data from the western Pacific seem to support the migratory hypothesis given by Kamimura and Honma (1963) to explain the cline in this region. That is, the western Pacific yellowfin appear to migrate from inshore to offshore areas as they grow. However the true causes of these clines are still not clear.

It was concluded that the concept of "semi-independent" subpopulations proposed by Kamimura and Honma (1963) and Royce (1964) defines the population structure of Pacific yellowfin. At least three stocks (i.e. western, central and eastern), relatively independent of each other, are thought to exist, but the actual number and location of subpopulations is still unclear. Possible north-south separations, indicated to some extent by genetic studies and tagging, could be neither substantiated nor rejected on the basis of this study.

Finally, unless some major change in the fishing technology occurs, it is doubtful if any significant sustainable increase in yellowfin production from the Pacific is possible. The greatest potential for increase, if any, appears to be based on changing the size structure of yellowfin in the catch from the central Pacific.

INTRODUCTION

Pacific stocks of yellowfin tuna, *Thunnus albacares*, until recently have been exploited primarily by the United States and Japan using three major fishing methods. The United States has used baitboats and purse seiners, both of which catch tunas at or near the surface, whereas Japan has traditionally used longline vessels, which catch tunas (and billfishes) at greater depths.

After World War II the Japanese longline fishery rapidly expanded eastward from the western Pacific, and by mid-1960 nearly the entire Pacific area inhabited by yellowfin was exploited by the fishery (Figure 1). Accordingly, the total catch of yellowfin by the Japanese longline fleet increased to about 70 thousand tons in 1961. However, since 1961 (except for 1966) the yellowfin catch by the Japanese longliners has shown a declining trend (Table 1). Taiwanese and South Korean longline fleets began to participate in this fishery in 1962 and 1965, respectively, but the total yellowfin catch did not increase despite the increased fishing effort (Honma, 1974).

Kamimura, Suda and Hayasi (1966) and Honma, Kamimura and Hayasi (1971) concluded that increases of longline effort over the level reached in the early 1960's would be accompanied by marginal increases or even decreases of the total catch. This conclusion seems to have been confirmed in the follow-up study by Honma (1974), which indicates that the average maximum sustainable yield for the Pacific yellowfin available to the longline fishery would be around 60 thousand tons (Figure 2).

By the end of the 1960's the surface fleets in the eastern Pacific, through conversion from baitboat fishing to modern purse seining, expanded the fishing area north of the equator to include most of the IATTC Yellowfin Regulatory Area (CYRA) (Figure 12). The IATTC first recommended regulation of yellowfin fishing in the CYRA in 1961. Curtailment of the total catch to 75,000 metric tons (83,000 short tons) was recommended by the Commission based on a production model calculation (IATTC, 1962). However, it was not possible for the participating countries to implement the regulations until 1966. Since 1968, the surface fishing grounds have expanded further offshore, moving into the area west of the CYRA (Figure 1). During the 1961-1974 period, contrary to the early prediction, the yellowfin catch by the surface fleets in the eastern Pacific increased remarkably, reaching about 211 thousand metric tons in 1974, including the catch from outside the CYRA (Table 1).

Despite the presence of large-scale fisheries in the Pacific, the population structure of yellowfin, in a Pacific-wide sense, is still unclear. (In this paper the word *population* means all of the yellowfin tuna in the Pacific Ocean; *subpopulation* means a subset of the population that is a self-sustaining genetic unit; *stock* means an exploitable subset of the population existing in a particular area and having some uniqueness rela-

tive to exploitation; and *population structure* implies the existence of subpopulations or stocks.) This situation may be explained by the fact that yellowfin in the CYRA have been regarded generally as a single, independent subpopulation different from the offshore fish (Schaefer, Chatwin and Broadhead, 1961; Joseph, Alverson, Fink and Davidoff, 1964) and, until recently, the important fishing grounds for the surface and sub-surface yellowfin fisheries did not overlap each other geographically.

However, a recent development in the purse-seine fishery in the eastern Pacific necessitates reexamination of the population structure of the species. Namely, coincident with the offshore expansion of purse-seine fishing beginning in 1966, the actual catch of yellowfin began to exceed substantially the original estimates of theoretical maximum sustainable catch. Concomitantly, during the period 1966-1974, the recommended quota was raised from 72,000 metric tons (79,300 short tons) in 1966 to 159,000 metric tons (175,000 short tons) in 1974 (IATTC, 1967 and 1975). Two reasons, among the various probable causes which are considered as significant in accounting for this phenomenon, are the geographical expansion of the fishery and an increase in the average size of the fish in the catch (IATTC, 1975). However, little is known about the relation between yellowfin inhabiting traditional coastal fishing areas and those in the offshore fishing grounds. Also, there is still some uncertainty about the subpopulation structure of yellowfin within the CYRA (Joseph *et al.*, 1964).

Since 1969, the surface fishing area outside the CYRA has produced some 20 to 40 thousand tons of yellowfin per year, roughly equal to the average annual yellowfin catch by Japanese longliners in the entire Pacific. This raises concern about the effect of this offshore purse-seine fishery on the stocks available to longline vessels in the western Pacific, and also possibly on the surface stocks inside the CYRA (that is, the interaction among the different kinds of fishing on the stocks). The present study is an attempt to clarify the Pacific-wide population structure of yellowfin in order to deal with this question.

ACKNOWLEDGEMENTS

Drs. James Joseph and Akira Suda provided us the opportunity to undertake this study. Helpful advice was given by Drs. Shoji Ueyanagi and Sigeiti Hayasi and by our colleagues in the Inter-American Tropical Tuna Commission and the Far Seas Fisheries Research Laboratory.

The authors also wish to express their gratitude to Prof. Shoji Saito and Mr. Eiji Hanamoto for their valuable information and suggestions.

HISTORICAL REVIEW

Joseph *et al.* (1964) reviewed the studies relevant to the population structure of the yellowfin stock in the eastern Pacific exploited by the surface fisheries. However, these authors omitted the comprehensive study

of the population structure of Pacific yellowfin by Kamimura and Honma (1963). There have been no general reviews on this subject since that date.

Most early studies were based on morphometric methods. Godsill (1948) and Godsill and Greenhood (1951) recognized four subpopulations, *i.e.* off Japan, Hawaii, Peru and in the northeastern Pacific. Schaefer (1955) stated that yellowfin in the vicinity of southeast Polynesia, Hawaii and in the eastern tropical Pacific belong to different subpopulations. Kurogane and Hiyama (1957) indicated that there were three subpopulations, *i.e.* in the western, central and eastern Pacific.

Yabuta, Anraku and Yukinawa (1958) and Kamimura and Honma (1963) hypothesized from a study based mainly on length-frequency data and catch-and-effort statistics of longline fishing that as yellowfin grow they migrate from the coastal areas of the western Pacific to the central Pacific. However, neither of these studies mentions any relationship between yellowfin tuna exploited by the eastern Pacific surface fishery and the longline fishery in the western and central Pacific. Yabuta *et al.* (1958) concluded that yellowfin tuna, at least west of about 150°W comprise one homogenous subpopulation. Some commentary is required to interpret Kamimura and Honma's (1963) conclusions. That is, although their original data showed that yellowfin west of about 120°W belong to one subpopulation, taking into consideration the results of morphometric studies, especially that by Royce (1961), they finally concluded that "the yellowfin population of the equatorial Pacific consists neither of a single, well-mixed homogeneous population nor of two or more highly independent groups, but is represented by a state intermediate between the two." Therefore they did not show any distributional boundaries for yellowfin subpopulations in the Pacific.

Honma *et al.* (1971) gave the following supplementary evidence indicating the migration of yellowfin from the western to the central Pacific: 1) The declining trend of density indices of yellowfin exploited by the longline fishery in the western Pacific (inhabited by young individuals) was more pronounced than that in the central Pacific (inhabited by older individuals), despite intense fishing effort exerted on the latter area. 2) The annual natural mortality coefficient calculated from the fish over 4 years old in the western Pacific was very high (2.5), but the same calculation including fish from the central as well as the western Pacific indicated a considerably lower estimate (1.2).

Joseph *et al.* (1964) assumed that yellowfin in the eastern Pacific (CYRA), were independent from yellowfin further westward, since the results of tagging experiments and morphometric studies implied little possibility of intermingling of the yellowfin tuna in an eastwest direction. However, they expressed some uncertainty about the degree of independence between inshore and offshore areas because of the apparently continuous

catch distribution of yellowfin tuna by Japanese longliners fishing east of 140°W.

Royce (1964), applying multivariate analysis to morphometric measurements of the species, came to the conclusion that "East-west migration is limited and most yellowfin remain within a few hundred miles of where they occur as juveniles." However, as in the case of Kamimura and Honma (1963), he could not show any spatiotemporal boundaries for subpopulations.

There have been several subpopulation studies of yellowfin based on immunological and biochemical methods (Suzuki, 1962; Sprague, 1967; Barrett and Tsuyuki, 1967; Fujino and Kang, 1968; and IATTC, 1971, 1973, 1974, 1975). However, it does not seem possible at present to make any generalizations from these studies. For example, transferrin studies by Barrett and Tsuyuki (1967) and Fujino and Kang (1968) did not indicate any heterogeneity in yellowfin sampled from various places of the eastern Pacific and from the Hawaiian-Line Islands area (possibly due to the small number of samples and the size of the samples). In contrast with this, recent transferrin studies indicate heterogeneity in yellowfin tuna within the eastern Pacific (IATTC, 1971, 1972, 1973, 1974, 1975). Fujino (1970), summarizing problems in methodology for this kind of study of tunas, pointed out the need to refine the quality of the samples (particularly with respect to homogeneity of the size of the fish examined) and to improve the techniques. In addition, the genetic studies of yellowfin are fragmentary (in the sense that geographic coverage is quite limited) and few systematic follow-up studies have been done. Therefore, to realize their great value in discriminating subpopulations directly, more extensive investigation is required.

It is probable that the major population studies of yellowfin have been affected considerably by artifacts resulting from certain characteristics of the fisheries. For example, the hypotheses of Yabuta *et al.* (1958) and Kamimura and Honma (1963) may be explained by the great mobility of the longline fleet and the apparent increase in the average size of fish in the catch from the west to the east along the equator. On the other hand, the conclusions reached by Joseph *et al.* (1964) for the eastern Pacific stock may be related partly to the fact that the surface fishery had been operating exclusively within the CYRA during the period of their study.

METHODS

The data used in our study are not based on direct genetic observations, but rather on other biological and fishery data, as was the case in other major studies of the population structure of yellowfin. In the following paragraphs we discuss the general problems encountered in a study of this type and methods by which the available data could be more

effectively utilized in the study of the population structure of yellowfin.

Hayasi (1967) pointed out in his review of the subpopulation studies on Pacific yellowfin that investigators have generally followed a similar pattern, starting with a comparative study of some specific characteristic of yellowfin, then a study of a number of other characteristics and finally a comparative study of developmental stages. He suggested that the problems raised in the three major papers on this subject (Kamimura and Honma, 1963; Royce 1964; and Joseph *et al.*, 1964) could be resolved by looking at individual results in the context of life history stages. Hayasi thought that by this method biases inherent in the fisheries could be more easily recognized. This is difficult for yellowfin, however, as this species shows less distinctive segregation within its habitat during different developmental stages of its life history than do such species as albacore, bluefin and southern bluefin (Honma and Hisada, 1971). In fact, data from longline fishing (Kamimura and Honma, 1963) show that the distribution of yellowfin is continuous along the equator, forming a narrow strip, and segregation by size within its habitat is not as clearly established as it is for the aforementioned three species. Furthermore, yellowfin spawn almost throughout the year in this region (Kikawa, 1966). In spite of the difficulties, this approach was adopted for the present study.

The other major difficulty is caused by biases in the data resulting from the fisheries themselves. In the two major fisheries exploiting yellowfin, the longliners catch relatively large individuals swimming in sub-surface layers, while purse seiners aim at surface schools which consist in general of either large or small fish, depending on whether or not they are associated with porpoise. Furthermore, generally speaking, good yellowfin fishing grounds for longliners are not productive for surface fisheries and *vice-versa*. Thus, it is inevitable that considerable bias may be involved in fisheries data, and it becomes necessary to compare carefully data obtained from different fisheries. To help resolve this problem, attention should be given to the fact that the reaction of fish to the same environmental conditions can change remarkably, depending on their physiological condition as well as their stage of development.

Sexual maturity and spawning

Since differences in area and time of spawning should be useful in differentiating subpopulations, it is one of the important types of data used in the present study. Most investigators have utilized a gonad index (an index relating the weight of the ovary to fish size) for studies of sexual maturation of tuna in the Pacific Ocean. Of particular relevance are those by Orange (1961) for yellowfin caught in the surface fishery of the eastern Pacific and by Kikawa (1959, 1962 and 1966) for yellowfin taken by longline in the western and central Pacific.

In our study we also have used the gonad index. Our material con-

sists mainly of longline-caught yellowfin. In some cases we compared the sexual maturation of these fish with those from surface fisheries.

Gonad indices of yellowfin caught by longline

Data were obtained from 58,258 yellowfin captured by research boats of the Fisheries Agency of Japan and local prefectural boats for the period 1970-1972. The latter consist of research vessels of the Fisheries Experimental Stations and training vessels of the fisheries high schools.

The gonad index (GI) was calculated as

$$GI = \frac{W}{L^3} \times 10^4$$

where W is the gonad weight of both lobes in grams and L is the fork length in centimeters. The indices were stratified by sex, 5-degree areas, quarters of the year, and by three length classes (80-100 cm, 101-120 cm and greater than 120 cm). The three length classes, representing immature, intermediate, and mature fish, respectively) were adopted on the basis of maturation studies of yellowfin caught by longline gear (Yuen and June, 1957; Kikawa, 1966). In addition, we compiled tables giving the relation between the size of fish and gonad index.

The geographical distributions of the gonad indices, by quarter of the year and major size groups, are shown in Figure 3 for both male and female yellowfin. In general, the GI increases in accord with increasing fish length, and the patterns of areal and seasonal changes of GI are independent of both sex and size class. Apart from the areas east of 110°W and the south-central Pacific (south of 10°S), where there are very few data, the major spawning areas are between 15°N and 15°S. The spawning areas appear to expand toward the higher latitudes in the vicinity of Hawaii in the northern summer and as far south as 25°S along the eastern coast of Australia in the southern summer.

In order to detect spawning activities, Kikawa and Honma (1975) used a deviation index (10 times the difference between an unadjusted mean GI and the standard value, taking GI values calculated only from specimens in the immature or resting condition as a standard). Since differences in the standard indices in different size classes of the Pacific yellowfin are small, Kikawa and Honma finally calculated a standard value of 0.8 for all size classes after rounding off the mean value of 0.75 (Table 2). Then deviation indices were computed for the same female yellowfin that were used in this study.

Two groups with relatively high deviation indices are noticeable (Figure 4), one in the western Pacific between 130°E and 170°E and the other in the central Pacific between 110°W and 160°W. The western group is located in the southern hemisphere whereas the central one seems to be mainly north of the equator. Spawning peaks seem to occur in the third and fourth quarters in the western Pacific and in the second

and third quarters in the central Pacific. However, the boundary between the two areas tends to become vague in the third quarter.

The present study corroborates observations of spawning seasons by Marr (1948) and Shimada (1951) for the western equatorial Pacific, by June (1953) and Yuen and June (1957) for the central Pacific, and by Kikawa (1966) in the western and central Pacific.

Although no break has been found in the geographic distribution of gonad indices of yellowfin tuna in the eastern Pacific based on data from the longline fishery (Kume and Joseph, 1969; Shingu, Tomlinson and Peterson, 1974), a recent study (Knudsen, 1977) on maturity of this species caught by purse-seine vessels indicated that there are intensive spawning areas outside the CYRA in addition to the already-described coastal spawning areas. However, as the data are sparse, especially along the CYRA boundary, further investigations are required to clarify the details of the spawning activities of this species in the eastern Pacific.

It is interesting to note that small 80-100 cm yellowfin with high deviation indices are found in coastal areas or in waters close to islands in the tropics (Figure 4). This phenomenon has been reported from the Marshall Islands (Marr, 1948), off the Philippine Islands (Bunag, 1956; cited from Kikawa, 1966), off central Mexico and Panama (Orange, 1961) and the Coral Sea (Hisada, 1973). However, these apparently precocious yellowfin tuna appear also in the area between 100°W and 140°W along 10°N in the central spawning area where virtually no islands exist. The relationship between the fork length and GI of female yellowfin is shown diagrammatically in Figure 6 for the areas outlined in Figure 5. According to this figure, the major spawning areas (Areas 6 and 7 in the western Pacific and Area 4 in the central Pacific) are characterized by high percentages of individuals with gonad indices of 2.1 or higher (Kikawa, 1962) and (sporadically) very high gonad indices in the spawning seasons.

Since longline and purse-seine fishing generally do not occur in the same areas, the only place where it was possible to compare the data from both fisheries simultaneously was the area outside the CYRA bounded by 5°N-10°N and 120°W-145°W. The longline data consist of 957 females collected from 1970-72, and the purse-seine data consist of 238 females collected in 1970, 1972 and 1973.

Although no data are available for purse seine-caught yellowfin in the first quarter, it is obvious that the percentages with gonad indices of 2.1 or greater in the same length class are considerably higher in the specimens caught by purse-seine gear than those by longline gear in all months (Figure 7). Both purse-seine and longline specimens show high percentages of mature fish from April to September with some minor differences in trend among length classes.

An apparent difference in the sexual maturity of yellowfin sampled by longline and surface (hand-lining) gear in the Coral Sea has been

reported by Hisada (1973). He hypothesized that mature yellowfin tuna come up near the surface to spawn in warmer water (26°C and higher) so that the surface fishing gear selectively catches fish which are sexually mature, whereas longline gear continues to catch fish that are less mature in deeper and cooler waters (except during the period when the water temperature becomes warmer than 26° at the catching depth of the longline gear).

To examine Hisada's hypothesis, profiles of the 26°C isotherm along 5°N and 10°N in the area under discussion were interpolated from temperature maps prepared by Robinson and Bauer (1971). It appears (Figure 8) that from about April to August, the 26°C isotherm is located below the minimum depth of longline hooks (approximately 50 m (Hisada, 1973)), whereas this isotherm is found above 50 m or completely lacking in the other months. Therefore, Hisada's hypothesis also seems applicable in the present case, that is, spawning fish seek temperatures greater than 26°C , and these temperatures occur at the depths that longlines fish only from about April to August or September. However, detailed studies with more adequate data are required to assess whether this apparent difference in sexual maturity of yellowfin tuna caught by different fishing gear remains consistent.

Distribution of larval yellowfin tuna

Japan's Far Seas Fisheries Research Laboratory (FSFRL) has been collecting data on larval tunas and billfishes for many years. The present study covers the larval samples collected aboard 3 governmental and 43 local prefectural vessels during 1956-1971, using surface horizontal tows, since this type of tow provided the largest number of the samples available. Data from horizontal surface tows for yellowfin tuna in the eastern Pacific (Klawe, 1963, Table 2) were added to the FSFRL data.

As there was no significant difference in the catches of yellowfin larvae in horizontal surface tows made at night and in the daytime (Ueyanagi, 1969), these two kinds of data were combined to calculate relative larval abundance. Although the towing speed of larval nets was fixed at about 2 knots, net diameter and towing time differed. Therefore, $1,012 \text{ m}^3$ of water strained was taken as one unit of tow. This volume of water is equivalent to that strained by a 1.4-m diameter net with approximately two-thirds of the opening submerged in water and towed for 15 minutes at 2 knots. The number of larvae per unit of tow was calculated for 5-degree areas, by quarter, regardless of the year.

There are three major areas with a high density of yellowfin larvae in the equatorial Pacific: the western area ($130^{\circ}\text{E}-170^{\circ}\text{E}$), the central area ($130^{\circ}\text{W}-160^{\circ}\text{W}$), and the eastern area (east of 110°W) (Figure 9). In northern summer, yellowfin spawning occurs as far north as 35°N along the Pacific Coast of Japan in the Kuroshio Current, and as far north as 30°N adjacent to Hawaii. Figure 9 also shows the subdivisions of the

Pacific which we used in examining seasonal changes in larval density. The subdivisions include practically all areas of the Pacific Ocean in which the surface temperature exceeds 26°C during all or part of the year (Ueyanagi, 1969). The quarterly average density of larvae was calculated only for 5-degree areas in which tows were made more than five or more times, (solid circles in Figure 9).

Seasonal peaks of larval density appear in the second quarter in Area 1, the fourth quarter in Areas 2 and 3, in the third quarter in Area 4, and in the second quarter in Area 5 (Figure 10). Though no data were obtained in the third quarter in Area 6, there appears to be a peak in the second quarter. None of the areas had peaks of larval density during the first quarter.

These results coincide fairly well with earlier studies on the spawning of this species (Matsumoto, 1958; Orange, 1961; Klawe, 1963; Kikawa, 1966; and Ueyanagi, 1969). However, there seem to be at least two differences. Comparison of the seasonal spawning peaks shown in our study and those shown in Kikawa's (1966) gonad study (his Figure 38) shows that there is some time lag in the occurrence of spawning peaks probably due to the sequential order of the phenomena. That is, the peak estimated by the gonad study generally precedes those calculated from the larval samples. For example, in Area 2 the density of the larvae reaches a maximum in the fourth quarter whereas the gonad study indicates that spawning is highest in the third quarter. The other difference is that estimates of the spawning potential by means of GI by Kikawa (1966) in the western equatorial Pacific were low in contrast to the central and eastern equatorial areas, whereas there seems to be no appreciable difference in the relative abundance of larvae along the equatorial zone, at least between the western and central equatorial Pacific (Figure 9). The cause of this latter difference is not clear. However, Kikawa (1966) points out three possible causes of bias involved in the estimation of his spawning index (K). Two of the possible causes (shortcomings in the geographic coverage of GI data and the choice of a possibly anomalous year in the estimation of abundance of the fish) do not seem serious enough to have changed the relative dominance of K between the two areas in question. However, the possible underestimation of spawning potential for smaller precocious yellowfin pointed out by Kikawa and also mentioned above seems to deserve further study. In the past, fish less than about 120 cm (which form an important part of the longline catch in the western Pacific) were thought to be too small to spawn. It is of interest to note that yellowfin with running ripe eggs reported from the western and central Pacific (Kikawa, 1966) were located approximately in the high-density areas of larvae discussed in this study.

Surface horizontal tows indicated considerably higher concentrations of larval yellowfin in the northeastern Pacific than in the western or central Pacific (Figure 10). Although yellowfin larvae were collected as

deep as 300 m (Matsumoto, 1958), most of the larvae are considered to occur above the thermocline (Klawe, 1963). However, even in areas where the thermocline is fairly deep, they tend to congregate within about 50 m of the sea surface (Matsumoto, 1958). In the northeastern Pacific the thermocline is extremely shallow (on the average, about 30 m in Klawe's larval sampling locations). Hence, it may be possible that the high concentration of larval yellowfin in the northeastern Pacific is due to an unusually shallow thermocline (*e.g.* the thermocline serves to concentrate the larvae). In other words, the present study, based on surface horizontal tows, may underestimate the relative larval abundance in the western and central Pacific.

Distribution

In this section, the geographical catch distribution of yellowfin is examined, using the data from the Japanese longline fishery which operates over almost the entire tropical Pacific and from the surface fishery (purse seiners and baitboats) operating in the eastern Pacific. The vertical distribution of this species is also briefly investigated comparing the results with those from earlier studies.

Distribution of yellowfin caught by the Japanese longline fishery

As an index of relative abundance of yellowfin available to longline gear, average catch rates (number of yellowfin caught per 100 hooks) were computed by month and 1-degree area for the 1967-1972 period.

Figure 11 shows the distribution of the average monthly catch rate. Generally it will be noted that areas with high catch rates are located along the equator, the rates being highest in the western equatorial areas and gradually decreasing toward the east. East of 140°W, two zones of the higher rates appear to the north and south of the equator in the first and second halves of the year, respectively. Catch rates in the coastal areas of the eastern Pacific are very low, except around 10°N in the first half of the year.

Seasonal changes in catch rates for the three major longline grounds are briefly described as follows:

1) West central equatorial region — This is defined as the area between about 5°N and 10°S and west of 140°W. However, it narrows to an area between 5°N and 5°S west of 180°. There are few seasonal changes in the distribution of catch rates in this region, except that rates between 170°E and 140°W decrease from about August to December. Moderately high catch rates extend from the western part of this region up along the Kuroshio Current (Figure 26) and curving down along the East Australian Current in accordance with the seasonal strength of these currents, although local patches of high catch rates off Sydney, Australia, seem to persist nearly all year.

2) Northeastern region — This is the area between 5°N and 10°N

and east of 140°W. There are two zonal areas of high catch rates in this region. The western area, located between 130°W and 140°W, had high rates from April to July. On the other hand, the eastern area, which appears along 10°N and between 85°W and 110°W, had high rates during December-June; however, the effort in this area was sparse during the other months.

3) Southeastern region — This is the area east of 140°W lying close to the equator in the western part and extending diagonally southeast to as far south as 20°S in the easternmost part. The area with highest rates is found in the eastern part of this region between about 85°W and 95°W. The area of high catch rates seems to shift its position southward from July to October.

Our study of the distribution of hook rates for yellowfin indicated a possible east-west break between about 110°W and 120°W. This break seems to occur also in data presented by Shingu *et al.* (1974), who used most of the same data used in this study. However, as mentioned previously, Joseph *et al.* (1964) could not find any breaks in the distribution of Japanese longline statistics for the area east of 140°W, based on data for April 1962 to May 1963. Kume and Joseph (1969) also could not show the break for similar data from 1964 and 1966. This discrepancy appears to have resulted mostly from the establishment of a relatively new longline coastal fishing ground in the northeastern region along 10°N. Though longline fleets covered almost the whole tropical Pacific by the first half of the 1960's, this new fishing ground was not exploited until the second half of the 1960's.

Distribution of yellowfin caught by the surface fishery in the eastern Pacific

Several studies have been made of the distribution of yellowfin caught by baitboats in the eastern Pacific during the period when the baitboat fishery was the major surface fishing method (Griffiths, 1960; Blackburn and Associates, 1962; and Broadhead and Barrett, 1964). Since this fishery was largely replaced by the purse-seine fishery during the early 1960's and is now operating only on a minor scale in coastal areas and around banks and islands, recent data on baitboats were examined only superficially.

In contrast to longliners, which operate continuously throughout the year over vast areas, even including areas of low abundance for yellowfin, the distribution of fishing effort by purse seiners in the eastern Pacific occurs in such a discontinuous fashion (especially since yellowfin fishing regulations were initiated in 1966) that it is difficult to obtain a true picture of the distribution of yellowfin available to the fishery. The distribution of the catch and catch per standard day's fishing do not seem to differ very much for unregulated trips, except in those marginal areas

where effort was light (Figure 12). Therefore, the areal and seasonal changes in areas fished by seiners as described here are based only on the distribution of the yellowfin catch from unregulated trips in which mainly yellowfin tuna were caught (Figure 13).

The seiner fishing grounds in the first quarter covered almost the entire CYRA north of the equator. (Recently, however, yellowfin fishing has expanded into areas as far south as 10°S.) Good catches were made off central and southern Mexico, off Costa Rica and in the vicinity of the Gulf of Guayaquil. During the years covered in this study (1965-1973) the yellowfin catch by seiners in the Panama Bight was poor except in 1973.

In the second quarter good fishing areas within the CYRA were roughly the same as in the first quarter, except that they expanded north off the coast of southern Baja California.

Since 1967, due to regulations the third-quarter catch has come mainly from outside the CYRA. Most fishing in this area occurs along 10°N as far west as 145°W. Inside the CYRA, yellowfin seem to be captured off southern Baja California and off southern Mexico, although almost no third quarter data were available except for 1965.

The catch from outside the CYRA along 10°N in the fourth quarter appears to be slightly lower than that of the third quarter. Good catches are also reported from the areas along 5°N just outside the CYRA and along 3°N (northern boundary of one of the experimental areas which was opened in 1973 (IATTC, 1974)). Within the CYRA fishing seems to occur along 10°N from the coastal area to farther offshore.

Throughout the years of this study there has been virtually no fishing effort immediately to the east of the CYRA boundary. Therefore, very little can be inferred about whether yellowfin tuna are accessible to surface fisheries in this area. There are no apparent environmental barriers to the capture of yellowfin here.

Vertical distribution of yellowfin

Little is known about vertical distribution of yellowfin due to lack of adequate methodology. However, attempts have been made by studying stomach contents (Watanabe, 1958) and hooking depths by longline (Watanabe, 1961).

The recent development in the western Pacific of a deep longline fishery aimed at catching bigeye in which longline hooks are set far deeper than ordinarily, is providing new information on yellowfin depth distribution. The maximum average hanging depth of ordinary longline is about 100 m (Honda, 1966) while that of the new deep line is about 200 m or deeper (Kamijo, 1962).

Catch rates for yellowfin caught by the regular and deep longlines in different areas are shown in Figure 14. These data seem to indicate that yellowfin catch rates calculated for these two fishing methods do not differ

appreciably. To confirm this observation, the mean catch rates of yellowfin by the two longline methods were tested statistically. As catch rates change very rapidly with latitude in this region, the test was made using data from latitudes in which the two fishing methods occurred simultaneously (*e.g.* test of difference in means for paired values). A two-sided test ($\alpha = 0.05$) indicated that the mean of the differences in catch rates for the two methods did not differ from zero ($t_0 = 1.00$, d.f. = 33). Thus yellowfin are caught about equally at all depths. Some reservation is necessary, however, since it is uncertain at what depths the fish are actually hooked. For example in deep sets, the fish may be caught at shallower depths while the hooks are sinking or being retrieved.

A more recent study (Suzuki, *et al.*, 1977) of similar data placed more emphasis on spatial-temporal comparisons and the influence of thermocline depth. They concluded that regular longlines may catch more fish than deep longlines, especially where the thermocline is above the average depth fished by the deep longline. Neither type of longline gear seems to be useful in determining a maximum depth for yellowfin or even a lower depth at which the density diminished significantly.

Relation between environmental conditions and the distribution of yellowfin caught by longline boats

Among the many studies of the relation between the distribution of yellowfin and environmental conditions, Nakamura's (1965) hypothesis dealing with intra-and/or inter-specific habitat segregation of tunas and billfishes within ocean currents should be cited here because of its generality. However, his hypothesis was developed mainly from studies of longline fishing in the western Pacific, and subsequently some difficulties have been noted in applying the hypothesis to other areas (Suda *et al.*, 1969; Yamanaka *et al.*, 1969). Kawai (1969) and Suda *et al.* (1969), who re-examined Nakamura's hypothesis and a similar idea by Yamanaka *et al.* (1969), suggested that vertical thermal structure (especially thermocline topography) is an important factor in approximating the distribution of the tunas. It is noted that thermocline topography also approximates other hydrographic characteristics.

On the basis of a study of the Atlantic longline fishery, Kawai (1969) proposed that the main fishing grounds for Atlantic yellowfin are characterized by two conditions: (1) the temperature of the surface mixed layer is high ($\geq 27^{\circ}\text{C}$) and (2) the mixed layer is quite thin, (islands found in the vicinity or areas with abundant tuna food might be substituted for this second condition.) It is interesting to see how Kawai's hypothesis applies to Pacific yellowfin. In those areas of the western and central Pacific where the first condition is met, there is generally a positive correlation between the presence of islands and high catch rates, but there are many open sea regions with high catch rates that have thick mixed layers. Unfortunately data on the abundance of food for yellowfin are

not available. The eastern Pacific was more carefully examined, since there are fewer islands and relatively sharp seasonal and areal changes of both temperature and thickness of the mixed layer for the region. Monthly maps of the surface temperature and thermocline depth prepared by Wyrtki (1964) were used. Kawai did not define what he meant by a shallow thermocline, so 50 m was arbitrarily selected as the maximum depth. Figure 15 shows schematically the correspondence, by months, between favorable areas for capturing yellowfin by longline and the actual distribution of high catch rates (≥ 1.51 , as in Figure 11). It is evident that little relationship exists between the occurrence of favorable areas, as defined by Kawai (1969) and high catch rates of yellowfin, especially during the last half of the year.

It is noteworthy that the longline fishery off Peru takes substantial amounts of yellowfin that is regarded as reproductively inactive or in a resting condition (Kume and Joseph, 1969; Shingu *et al.*, 1974). This seems to imply the possibility of using gonad developmental stages as an aid in explaining the distribution of the species more thoroughly.

Trends in density indices of yellowfin caught by Japanese longline boats

Kamimura *et al.* (1966) and Honma *et al.* (1971) pointed out that yellowfin hook rates for Japanese longline fleets in the western Pacific west of 180° did not show any declining trend, at least in the period from the inception of the fishery in the late 1940's to about 1960, whereas in the central-eastern Pacific east of 180° , a clear decline in the hook rate was indicated from the very beginning of the fishery. As mentioned previously, it was concluded that the lack of decline in the density indices in the western Pacific is due to recruitment of small fish into the longline fishery in this region; however, as the fish grow and subsequently move eastward, they are exposed to successively greater exploitation, in the central and eastern Pacific, thus producing the declining trend in the central area.

Adding recent data and using smaller subdivisions of major fishing grounds (Figure 16), annual average density indices were calculated as follows:

$$\hat{d} = \frac{1}{m} \sum_{i=1}^m \left(\frac{N_i}{A_i} \right) = \frac{1}{m} \sum_{i=1}^m \left(\frac{\sum_{j=1}^n \frac{(C_{ij} A_{ij})}{g_{ij}}}{\sum_{j=1}^n (A_{ij})} \right)$$

Where \hat{d} = annual average density index in a particular major fishing ground of a particular year,

m = number of quarters during which fishing was conducted,

N_i = stock size index in the i th quarter,

A_i = extent of the fishing area during the i th quarter,

- C_{ij} = catch in number from the j th 5-degree area unit within the major fishing ground in the i th quarter,
 g_{ij} = nominal effort in terms of the hooks set in the j th 5-degree area unit within the major fishing ground in the i th quarter, and
 A_{ij} = relative area index in the j th 5-degree area unit (Honma *et al.*, 1971) in the i th quarter.

The apparent difference in the trend of declining density indices between the western and the central-eastern Pacific indicated by the previous studies is not observed so clearly in the present study (Figure 17). Addition of the more recent data seems to have lessened the apparent difference between the two regions. It is noteworthy that the trends of declining density indices in Areas E₁, E₂ and E₃, the principal longline fishing grounds in the western Pacific, closely resemble each other.

Length composition of yellowfin caught by longline

Only the Japanese longline data were used due to lack of adequate data from the Taiwanese and South Korean longline fisheries. We used the catch in numbers of fish for the period 1966-1972, tabulated by quarters, areas of 5° of latitude by 10° of longitude, and 2-cm length intervals. To estimate the length composition of the catch in each 5° x 10° area, the length-frequency samples were weighed by the corresponding catch in numbers as compiled by the Fisheries Agency of Japan (1968-1974).

The estimated length-composition data of the catch, by quarters, were grouped into three major areas, northern (10°N-25°N), middle (10°N-5°S) and southern (5°S-25°S), and are shown by intervals of 10° longitude for all areas east of 130°E (Appendix Table 1). In Appendix Table 1 area 130°E, for example, denotes the area 130°E to 140°E, while area 130°W denotes 130°W to 140°W. All 10° areas east of 120°W to the coastline were combined and this is indicated by the sign <110°W in Appendix Table 1. The length compositions of the fish of these three major areas were further combined across years for the 1966-1972 period by major area and by intervals of 10° longitude (Figure 18). Also the data were combined into six major areas (Figure 19).

Though there are yearly variations in areal patterns of the length-composition, it can be noted that there is a consistent tendency for large individuals to become increasingly dominant from west to east in the three major areas (Figure 18). However, in the areas east of 120°W, small fish less than about 100 cm appear at times in appreciable numbers. Incidentally, the prominent mode at about 100 cm in the southern area east of 120°W in the third quarter (Figure 18) is due almost entirely to the catch in 1972 (Appendix Table 1). In the northern and southern areas, large fish are generally more dominant than in the middle area for areas of the same longitude, except for the areas east of 130°W (Figure 19).

The present study confirmed a progressive longitudinal change in

length composition of yellowfin caught by longline gear reported by Yabuta *et al.* (1958) and Kamimura and Honma (1963). However, it is noteworthy that small fish ranging from about 80 cm to 100 cm which are abundant in the catch in the western Pacific, but rather rare in the central and eastern Pacific, are appreciable in the catch from the areas east of about 160°W in some years (Appendix Table 1). Their appearance in the central and eastern Pacific does not seem to have been mentioned by either Yabuta *et al.* (1958) or Kamimura and Honma (1963), probably because of the following reasons. In the former study, the longline fishery had not yet operated full scale in the central Pacific, nor at all in the eastern Pacific, and the samples from the central Pacific were few and obtained mostly in the fourth quarter, when larger yellowfin dominated. (Figure 18). In the latter study, the length compositions were calculated by quarter, but samples were summed across years. Since small fish did not occur in the samples in every year and their numbers relative to the total catch are not large, combining data for years should diminish their relative numbers in the length compositions. In fact, when the data are computed by quarter combining the years as in Figure 18, the small fish in the central and eastern Pacific are indicated as only a minor fraction in the length compositions (except in the southern area east of 120°W in the third quarter as mentioned above). It is not possible to interpret such catches of small yellowfin as being related to their proximity to islands (where small fish usually congregate), since the area north of 5°S and east of 150°W is virtually free of islands. Besides, as will be mentioned later, purse-seine fleets in the eastern Pacific operating in the offshore areas between about 120°W and 150°W along 10°N catch substantial amounts of fish of this size, as well as larger individuals. Therefore, their occasional appearance in the longline length compositions in those areas should not be considered as merely bias in the sampling.

Length composition of yellowfin caught by purse-seine in the eastern Pacific

Length compositions of yellowfin catches in terms of weight by the purse-seine fleet in the eastern Pacific were computed for the CYRA and outside the CYRA over the period 1966-1972 and 1969-1974, respectively. The weight frequencies rather than the numerical frequencies were used to obtain modes of more nearly equal height. This should have little effect on modal positions. These length-frequency compositions were combined across years and grouped by quarter and by major areas (Figure 20) within which the length samples are generally similar. There is a tendency in the CYRA, and to a lesser degree outside the CYRA, for larger fish to become increasingly dominant from inshore to offshore areas (Figure 21). However, the gradient of this tendency in terms of distance from the coast does not seem to be the same in different latitudinal zones. That is, in zones N₂ (10°N - 20°N) and N₃ (0° - 10°N) yellowfin above 120 cm are caught in substantial amounts near shore (*e.g.*, in Figure 20, Areas 3, 4

and 10), whereas such large individuals rarely appear in the coastal areas of the adjacent zones N₁ (20°N - 35°N) and S (0° - 20°S) except in the first quarter in Area 18 and 19.

It should be noted for the length compositions outside the CYRA that in addition to the dominant larger fish, small fish under about 80 cm are caught in relatively large amounts around the third quarter. Note especially the occurrence of small fish ranging from 40 to 60 cm in the third quarter in Area 16. However, there is a possibility that some of these small fish might be improperly reported as catches outside the CYRA. Sizes of yellowfin caught farthest offshore (Area 17) seem to be predominantly large, although the data available are sparse.

DISCUSSION

As noted above, our study on relative yellowfin larval abundance indicates three apparently high-density areas (western, central and eastern Pacific). Analyses of sexual maturity based on gonad indices of yellowfin sampled from the longline and purse-seine fisheries also indicate intensive spawning activities in those three areas. However, except for the distribution of longline catch rates, which showed an apparent break roughly corresponding to the one between the central and eastern areas mentioned above, no results were obtained from the investigations of length data or catch and effort data of either longline or surface fisheries that suggest the existence of isolated stocks or subpopulations of yellowfin.

In the following discussion, results of the different analyses are compared and interrelated.

The east-west cline observed in longline length-composition data

The gradual size increase of yellowfin caught by longline boats from west to east along the equator is a consistent phenomenon, apart from the occasional appearances of small fish in the central and eastern Pacific. This cline has played an important role in the studies of yellowfin in the Pacific, and the phenomenon has in fact been interpreted in two different ways. One is that yellowfin migrate from the western Pacific (inshore) to the central Pacific (offshore) as they grow (Kamimura and Honma, 1963). The other, based on a morphometric study (Royce, 1964), attaches limited importance to migration of the species. This second model attributes the cline to differential selectivity of the longline gear to the size of the fish in relation to the depth of the thermocline (Suda and Schaefer, 1965). It is based on the hypotheses that yellowfin have their main habitat within the mixed layer and that most of the larger yellowfin inhabit the deeper part of the mixed layer (close to the top of the thermocline) so that longline hooks set at roughly a constant range of depth become gradually more effective from the western Pacific to the eastern Pacific in catching the larger individuals in accordance with the eastward shoaling of the upper

mixed layer. From the information in the previous section on vertical distribution, the Suda and Schaefer (1965) hypothesis that the main habitat for yellowfin tuna is above the thermocline can be considered a plausible one. However, it is difficult to find any information with which to assess the soundness of their second hypothesis on vertical segregation of habitat by size of the fish.

Since longline gear generally does not catch substantially greater amounts of small yellowfin (80 cm to 100 cm) in the eastern Pacific than in the western Pacific despite a higher abundance of this size range in the eastern Pacific, it is certain that size selectivity of longline gear changes depending on the area.

Comparison of the longline and purse-seine fishing grounds for yellowfin tuna in the Pacific shows an inverse relationship. The principal fishing grounds for longline fishing are situated in the western and central tropical Pacific, but only in a limited area in the eastern Pacific, while the reverse is true of seining grounds. At the time when Suda and Schaefer (1965) compared yellowfin length-composition data, this relationship was distinctive, *i.e.* these two fisheries seldom operated in the same areas. Such is no longer the case. Therefore, we decided to compare the length-composition data from the two fisheries for spatio-temporal strata in which the two fisheries operate simultaneously.

Length-composition data of the two fisheries obtained from the same $5^{\circ} \times 10^{\circ}$ areas in the same months of the same years were chosen. Data were available for 16 area-month strata within the CYRA for 1967-1969 and for 13 area-month strata outside the CYRA for 1969-1971 (Figure 22). Differential selectivity by longline gear for large yellowfin is still suggested, although the differences in the length compositions between the two fisheries appear to be less in these data than in those of Suda and Schaefer (1965, Figure 14). Incidentally, there is some doubt as to whether or not the fish smaller than about 75 cm reported here as caught outside the CYRA by the purse seiners, were actually caught there.

Despite lack of direct evidence on the vertical segregation of fish by size, Suda and Schaefer's explanation for the east-west cline in the length of yellowfin caught by longline gear seems plausible for the central and eastern Pacific, where the gradient of thermocline depth in an east-west direction is especially pronounced. However, this explanation does not seem to apply to the western Pacific, since the thickness of the mixed layer there barely changes in an east-west direction between about 130°E and 180° ; in fact it may even become deeper from west to east in this area (Figure 23). Nevertheless, the length composition of longline-caught yellowfin in the western area still shows an increase in the portion of large individuals toward the east. In addition, there is no indication that yellowfin caught in the western equatorial Pacific by the deep longline are appreciably larger than those caught by the regular longline (Yukio Warashina, personal communication).

Therefore, the extent of yellowfin migrations is of great importance to the discussion of the different interpretations of the cline observed in the length composition data from longline fishing. However, before discussing the extent of migrations, the inshore-offshore changes in the length composition of yellowfin obtained from the eastern Pacific purse-seine fishery will be briefly examined.

Length composition of yellowfin caught by purse-seine in the eastern Pacific

An increase in the portions of large individuals in the purse-seine catches of yellowfin from inshore to offshore areas (east to west) was indicated by samples from these catches in the eastern Pacific, although not so clearly as in the longline data. Two hypotheses have been given (IATTC, 1976) to explain this tendency: 1) offshore migration of yellowfin as they grow and 2) size selectivity in the fishery. Recent analyses of tagging data indicate that the second hypothesis is the more plausible one (IATTC, 1977).

The second hypothesis may be used to explain the inshore-offshore trend in the following manner. It is known that yellowfin caught by purse seine in association with porpoise are generally larger than those caught by other methods of purse seining. Also, most of the catches from schools not associated with porpoise are made in inshore areas, whereas catches from schools associated with porpoise account for the major portion of the offshore catch. This situation must contribute significantly to the longitudinal gradient in the length samples obtained from the purse-seine fishery. However, since both purse-seines and longlines selectively catch large yellowfin in the offshore areas, it appears that there is no effective method at present for examining the abundance of small fish less than about 80 cm. Therefore, it is not certain that the second hypothesis is the correct one.

Extent of migration

Tagging experiments of yellowfin exploited by the surface fisheries in the eastern Pacific have been conducted for many years. Analysis of data for fish recovered up to 1965 indicated that yellowfin tuna migrate on a large scale along the coastal regions in the CYRA (Fink and Bayliff, 1970). The extent of inshore-offshore (east-west) migration was not revealed by these experiments, however, because until about the middle 1960's the surface fleets had been fishing only near coastal areas and a few offshore islands. However, since no tag recoveries were made outside the CYRA by the Japanese longliners that were operating over offshore areas contiguous to and partly overlapping the surface fishing grounds it was believed that there were no large-scale inshore-offshore movements (Schaefer *et al.*, 1961; Joseph *et al.*, 1964).

The results of the analysis of more recent tag recovery data (Bayliff and Rothschild, 1974; IATTC, 1977) indicate that there is not a strong

tendency for yellowfin to move offshore as they get older. However, this can be verified only by obtaining more tag return data and by a more even geographical and temporal distribution of fishing effort.

The previously mentioned morphometric studies do not indicate sufficient east-west migration to result in intermingling of many fish between the eastern and the central Pacific.

In the western and central Pacific, very few yellowfin tagging experiments have been carried out so far, mainly due to the inadequacy of long-line gear (the major fishing method for yellowfin in this region) for this purpose. Experimental tagging cruises have been conducted, taking advantage of handline fishing on banks in the tropical western Pacific. However, tagged fish were recaptured close to the release points, and all within one year after their release (Kikawa, 1971). As Schaefer *et al.*, (1961) have pointed out, tuna tagged near fishing banks tend to disperse very slowly. Thus these tagging experiments appear to be inadequate for detecting the extent of migration. However, unpublished data from the Tohoku Regional Fisheries Research Laboratory indicate that a yellowfin tagged at 9° 56'N, 137°30'E was recaptured at 32°57'N, 136°40'E, and unpublished data from the Far Seas Fisheries Research Laboratory indicate that a yellowfin tagged at 26°25'S, 154°15'E was recaptured at 36°26'S, 150°13'E. These long-distance movements partially support the hypothesis of yellowfin migration along the Kuroshio and the East Australian Currents (Figure 26), as suggested from the distribution of the longline catch rates.

Movement of yellowfin in the western Pacific inferred from the distribution of tunas and billfishes contaminated by radioactivity

The Japanese government carried out various investigations, including some on tunas and billfishes, to examine the magnitude of environmental contamination by nuclear tests carried out by the U.S.A. from March 1 to May 5, 1954, at Bikini Atoll (Fisheries Agency of Japan, 1955). Analyses of the distribution of contaminated tunas and billfishes, combined with knowledge of their general distribution seems to justify the use of these data for at least a qualitative study of the movements of yellowfin (Fisheries Agency of Japan, 1955; Suda, 1956).

Table 3, taken from the study by the Fisheries Agency of Japan (1955), shows the percentage of contaminated fish and the numbers of fish examined, in major ocean currents, by species. This table shows that:

- 1) Hardly any contaminated specimens of striped marlin, *Tetrapturus audax*, or albacore, *Thunnus alalunga*, were found in the southern hemisphere. Each of these is assumed to belong to different subpopulations than its counterpart in the northern hemisphere (Ueyanagi, 1966). None of these species spends a significant amount of time in the North Equatorial Current (Figure 26), where the Bikini Atoll is located.
- 2) On the other hand, contaminated specimens of yellowfin, blue

marlin, *Makaira nigricans*, and sailfish, *Istiophorus platypterus*, which do not seem to be confined to equatorial currents, appeared in large numbers over vast areas.

In addition, the length compositions of contaminated yellowfin throughout the North Equatorial and Equatorial Counter Currents (composed of individuals larger than 110 cm) are roughly the same as those of the catch from that area of the two currents (between 150°E-170°E) which encompasses Bikini Atoll (Figure 24). These facts suggest that the contamination of yellowfin occurred in a relatively restricted area in the tropics.

In the previous reports on this subject, details on the occurrence of the contaminated fish were shown by combining data for all species. For our study we selected the data for yellowfin sampled at Tokyo, Misaki and Yaizu fish markets (major unloading ports for longline boats). Unfortunately, sampling was conducted only for 1954 and was limited mostly to the western Pacific. These data indicate that contaminated yellowfin appeared over nearly the whole western Pacific (Figure 25), indicating considerable mixing of yellowfin in this area.

Therefore, it can be hypothesized that the longitudinal cline in the length data from the longline fishery in the western Pacific reflects size-specific movements of yellowfin from coastal to offshore areas. However, this hypothesis is still inconclusive, and further evidence is required to prove it.

Considering all the available information, yellowfin probably migrate on a larger scale than a few hundred miles, especially in an east-west direction, as estimated by Royce (1964). However, the extent of migration does not seem to be sufficient to allow much mixing between the eastern and central Pacific, and probably not much between the western and central Pacific either.

CONCLUSIONS

None of the data used in this study (which covered the Pacific east of about 130°E) indicates any clear-cut discontinuity in the Pacific yellowfin population, but the data seem to support the concept of "semi-independent" stocks with some mixing as proposed by Kamimura and Honma (1963) and Royce (1964). Also, it should be pointed out that the three stocks mentioned are composed possibly in turn of subpopulations which cannot be discriminated by indirect kinds of data obtained through the fisheries as used in this study. If such subpopulations do exist it is suggested that even direct genetical study of the catch will not delineate their spatio-temporal extent.

Homogeneity of yellowfin inhabiting the region between about 120°E and 180° is indicated by long-term trends of the catch rates in the major longline fishing grounds and the occurrence of fish contaminated by radio-

activity over vast areas in the western Pacific. In addition to these observations, studies of larval distribution and sexual maturation show fairly discrete spawning activity in the areas west of about 180°. Therefore, taking into account the relatively restricted extent of migration for this species, yellowfin in the western Pacific between about 120°E and 170°W are considered to belong to a single stock and are probably being fully exploited by longline.

Furthermore, the view of an independent stock of yellowfin in the CYRA of the eastern Pacific is regarded as a reasonable assumption, judging from the distribution of larvae, the distribution of catch rates, and the movements of tagged fish. The IATTC has estimated that yellowfin production in the CYRA is near the maximum with present methods of exploitation.

Although there is little evidence to indicate positively the presence of a stock in the central Pacific, the authors tentatively assume that the yellowfin in this area form a different stock from either the western or the eastern Pacific ones. Since the yellowfin which are caught from the central Pacific are usually quite large, the central Pacific yield could probably be increased by lowering the average age in the catch and increasing total fishing mortality.

ESTRUCTURA DE LA POBLACION DEL ATUN ALETA AMARILLA DEL OCEANO PACIFICO

por

Z. Suzuki¹, P. K. Tomlinson² y M. Honma³

EXTRACTO

Se examinó la estructura de la población y la producción del atún aleta amarilla del Pacífico *Thunnus albacares* para estudiar la mayoría de los datos básicos que se tenían sobre el avalúo de la población, como también otra información correspondiente al periodo de 1965-1972. Los datos fueron obtenidos principalmente de las pescas palangreras japonesas del Océano Pacífico al este de los 120°E y de las pescas con redes de cerco del Pacífico oriental, al este de los 140°W. No se emplearon los datos de estudios genéticos de las subpoblaciones porque eran más bien preliminares.

El examen de los datos sobre la madurez de las gónadas y la distribución de larvas indicaron tres zonas relativamente diferentes con una actividad intensiva de desove a lo largo de la zona ecuatorial, es decir, el Pacífico occidental, central y oriental. Se encontró que la madurez sexual de las hembras de aleta amarilla capturadas en la pesca palangrera era diferente a la de las capturadas con redes de cerco y se trató de explicar esta diferencia, basados en la estructura térmica del océano.

Ni los datos de la talla, ni los de captura por unidad de esfuerzo de las dos pesquerías, indicaron una descontinuidad apreciable este-oeste, aunque parece que en la mayoría de los meses las capturas palangreras entre más o menos los 110°W y 120°W no son tan grandes como en otras partes. Los cambios a largo plazo en los índices palangreros de captura en varias de las regiones principales de pesca del Pacífico occidental fueron generalmente similares. Basados en un breve examen de su distribución vertical, parece que el atún aleta amarilla vive principalmente en la capa mixta. Además, se examinó brevemente la relación entre las regiones de pesca palangreras del atún aleta amarilla y las condiciones físicas oceanográficas.

Conforme a las muestras frecuencia-talla obtenidas de atunes aleta amarilla capturados con palangre y en menor grado por embarcaciones cerqueras, se indicaron los cambios progresivos este-oeste en la talla de captura. Con el fin de analizar el significado de este fenómeno, se examinó el grado de desplazamiento de este especie. Se incluyeron en este examen los datos sobre la aparición de peces contaminados por radioactividad durante experimentos con explosivos atómicos. Se decidió que el grado de desplazamiento era superior al calculado por Royce (1964), pero probablemente no tan extenso como para resultar en una entremezcla substancial entre los atunes aleta amarilla de la zona occidental, central y oriental del Pacífico. La inclinación evidente en los datos de talla en la pesca palangrera del Pacífico central y oriental, fue considerada como un fenómeno causado por la selectividad diferencial de talla de las artes pesqueras con relación a la topografía de la termoclina (Suda y Schaefer, 1965). Los datos del Pacífico occidental parecen apoyar la hipótesis de desplazamiento provista por Kamimura y Honma (1963), para explicar la inclinación en los datos de talla en esta región. Es decir, parece que el atún aleta amarilla del Pacífico occidental se desplaza de las zonas costeras a las oceánicas a medida que crecen. Sin embargo, la causa verdadera de esta inclinación no es aún evidente.

Se concluyó que el concepto propuesto por Kamimura y Honma (1963) y Royce (1964) de subpoblaciones "semiindependientes" define la estructura de la población

del aleta amarilla en el Pacífico. Se cree que existen por lo menos tres existencias (*e.d.* la occidental, central y oriental), relativamente independientes la una de la otra, pero no se conoce con certeza cuantas subpoblaciones hay y dónde se encuentran. La posible separación norte-sur, indicada, hasta cierto punto, por los análisis genéticos y del marcado, no puede ni confirmarse ni rechazarse basados en este estudio.

Finalmente, a no ser que ocurra algún gran cambio en la tecnología pesquera es dudoso que sea posible obtener un aumento constante e importante en la producción del aleta amarilla del Pacífico. El potencial mayor de aumento, si es que existe alguno, parece que se basa en el cambio de la estructura de talla en la captura del aleta amarilla del Pacífico central.

INTRODUCCION

Hasta hace poco tiempo, la población del atún aleta amarilla, *Thunnus albacares*, había sido explotada principalmente por los Estados Unidos y el Japón usando tres métodos principales de pesca. Los Estados Unidos han usado barcos de carnada y cerqueros (con ambas artes se pesca atún en la superficie o cerca a ésta) mientras que el Japón ha usado tradicionalmente embarcaciones palangreras, que pescan atunes (y peces espada) a mayores profundidades.

Después de la segunda guerra, la pesca palangrera japonesa se extendió rápidamente del Pacífico occidental al oriental, y a mediados de 1960 casi toda la zona del Pacífico en la que vive el aleta amarilla era explotada por la pesca (Figura 1). Por consiguiente, en 1961, la captura total de aleta amarilla obtenida por la flota palangrera japonesa aumentó a unas 70 mil toneladas. Sin embargo, desde 1961 (con excepción de 1966) la captura de esta especie obtenida por palangreros japoneses indica una tendencia descendente (Tabla 1). Las flotas palangreras de Taiwan y Corea del Sur empezaron a participar en esta pesca en 1962 y 1965, respectivamente, pero la captura total de aleta amarilla no aumentó a pesar de que se incrementó el esfuerzo pesquero (Honma, 1974).

Kamimura, Suda y Hayasi (1966) y Honma, Kamimura y Hayasi (1971), deducieron que si se incrementaba el esfuerzo palangrero sobre el nivel alcanzado a principios de los años sesenta, ésto resultaría en aumentos marginales o aún en reducciones de la captura total. Parece que esta conclusión fue confirmada por el siguiente estudio de Honma (1974) quien indica que el promedio máximo constante de producción de aleta amarilla que se podría obtener por la pesca palangrera en el Pacífico sería de unas 60 mil toneladas (Figura 2).

A fines de los años sesenta, las flotas epipelágicas del Pacífico oriental, reacondicionaron sus embarcaciones de carnada a la pesca moderna con redes de cerco y extendieron sus maniobras pesqueras al norte del ecuador, abarcando la mayor parte del Área Reglamentaria de la CIAT de Atún Aleta Amarilla (ARCAA) (Figura 12). En 1961, la CIAT recomendó por primera vez la reglamentación de pesca para el aleta amarilla capturado en el ARCAA. La Comisión recomendó un límite total de captura de 75,000 toneladas métricas (83,000 toneladas americanas), basándose en el cálculo

de un modelo de producción (IATTC, 1962). Sin embargo, no fue posible que los países participantes hicieran vigentes las reglamentaciones hasta 1966. Desde 1968, la pesca epipelágica se había extendido aún más mar adentro, trasladándose a una zona al oeste del ARCAA (Figura 1). Durante el período de 1961-1974, al contrario de los primeros pronósticos, la captura de aleta amarilla obtenida por la flota epipelágica en el Pacífico oriental aumentó notablemente, alcanzando unas 211 mil toneladas métricas en 1974, incluyendo la captura fuera del ARCAA (Tabla 1).

A pesar de la presencia de grandes pescas en el Pacífico, no se puede definir aún claramente la estructura de la población del aleta amarilla, con respecto a su distribución general en el Pacífico. (En este estudio, la palabra *población* significa todo el atún aleta amarilla del Océano Pacífico; *subpoblación* un subgrupo de la población que es una unidad autónoma genética; *existencia* un subgrupo explotable de la población que habita en una zona especial y que tiene una particularidad con relación a la explotación y *estructura de la población* la existencia de subpoblaciones o existencias). Esto puede explicarse por el hecho de que esta especie en el ARCAA, ha sido considerada generalmente como una subpoblación individual e independiente, diferente a la de aquellos peces que se encuentran más al oeste (Schaefer, Chatwin y Broadhead, 1961; Joseph, Alverson, Fink y Davidoff, 1964) y solo recientemente, es que las zonas importantes de la pesca superficial y subsuperficial se han sobrepuerto la una a la otra geográficamente.

Sin embargo, una reciente reforma en la pesca con cerco en el Pacífico oriental hace que sea necesario examinar de nuevo la estructura de la población de esta especie. La captura de aleta amarilla empezó a exceder substancialmente los cálculos originales de la captura teórica, máxima constante, justamente en la época de la expansión mar afuera de la pesca cerquera que se produjo de 1966 en adelante. Al mismo tiempo durante el período de 1966-1974, se aumentó la cuota recomendada en 1966, de 72,000 toneladas métricas (79,300 toneladas americanas) a 159,000 toneladas métricas (175,000 toneladas americanas) en 1974 (IATTC, 1967 y 1975). Existen dos razones entre las varias que se consideran importantes para explicar este fenómeno que son la expansión geográfica de la pesca y el aumento en el promedio de talla de los peces en la captura (CIAT, 1975). Sin embargo, se conoce muy poco sobre la relación que existe entre el aleta amarilla que habita las zonas pesqueras costeras, tradicionales y el que habita las zonas más oceánicas. Además, existe cierta duda sobre la estructura de la subpoblación del aleta amarilla que habita la zona del ARCAA (Joseph *et al.*, 1964).

Desde 1969, la zona epipelágica de pesca fuera del ARCAA ha producido de 20 a 40 mil toneladas de aleta amarilla anualmente, casi igual al promedio anual de captura de esta especie, obtenido por los palangreros japoneses en todo el Pacífico. Esto causa cierta preocupación sobre las consecuencias que esta pesca cerquera de altura pueda tener sobre las existencias disponibles a las embarcaciones palangreras en el Pacífico.

occidental y posiblemente también sobre las existencias de aguas superficiales en el ARCAA (es decir, la interacción entre las diferentes clases de pesca sobre las existencias). Con el fin de resolver este dilema, este estudio trata de explicar la estructura de la población del aleta amarilla en todo el Pacífico.

RECONOCIMIENTO

Le agradecemos a los Dres. James Joseph y Akira Suda por habernos dado la oportunidad de emprender este estudio. Recibimos consejos útiles de los Dres. Shoji Ueyanagi y Sigeiti Hayasi como también de nuestros colegas de la Comisión Interamericana del Atún Tropical y del Far Seas Fisheries Research Laboratory.

Los autores desean además expresar su agradecimiento al Prof. Shoji Saito y al Sr. Eiji Hanamoto por su valiosa información y consejo.

ANALISIS CRONOLOGICO

Joseph *et al.*, (1964) examinaron los estudios referentes a la estructura de la población de las existencias de aleta amarilla, explotadas en el Pacífico oriental por la pesca epipelágica. Sin embargo, omitieron un estudio muy completo sobre la estructura de la población del aleta amarilla en el Pacífico de Kamimura y Honma (1963). Desde esa época no se ha realizado una investigación general sobre este tema.

La mayoría de los primeros estudios se basaron en métodos morfométricos. Godsil (1948) y Godsil y Greenhood (1951), reconocieron cuatro subpoblaciones, es decir a la altura del Japón, Hawái, Perú y en el Pacífico noreste. Schaefer (1955) declaró que el aleta amarilla que se encuentra adyacente a la Polinesia sudeste, Hawái y el Pacífico oriental tropical pertenece a diferentes subpoblaciones. Kurogane y Hiyama (1957) indicaron que existían tres subpoblaciones, las del Pacífico occidental, central y oriental.

Yabuta, Anraku y Yukinawa (1958), y Kamimura y Honma (1963), mediante un estudio basado principalmente en los datos frecuencia-talla y en las estadísticas de captura y del esfuerzo palangrero de pesca, raciocinaron que a medida que el aleta amarilla crece, se desplaza de las zonas costeras del Pacífico occidental al Pacífico central. Sin embargo, ninguno de estos estudios menciona que exista alguna relación entre el aleta amarilla explotado por la pesca epipelágica del Pacífico oriental y el explotado por la pesca palangrera en el Pacífico central y occidental. Yabuta *et al.* (1958), determinaron que el aleta amarilla, por lo menos al oeste de los 150°W, forma una subpoblación homogénea. Es necesario hacer algunos comentarios al interpretar las definiciones de Kamimura y Honma (1963). Es decir, aunque los datos originales de estos autores indicaron que el aleta amarilla que se encuentra al oeste de los 120°W pertenece a una subpob-

lación, al considerar los resultados de los estudios morfométricos, especialmente los de Royce (1961), ellos concluyen que "la población del aleta amarilla del Pacífico ecuatorial no está formada ni por una población homogénea individual bien mezclada, ni por dos o más grupos independientes, pero que está representada por una etapa intermedia entre estos dos conceptos." Por consiguiente, no indican ningún límite de distribución para la subpoblaciones del aleta amarilla en el Pacífico.

Honma *et al.* (1971), presentaron otra prueba en la que indican el desplazamiento del atún aleta amarilla del Pacífico occidental al central: 1) la declinación en los índices de densidad del aleta amarilla explotado por la pesca palangrera en el Pacífico occidental (donde viven los individuos jóvenes) fue más marcada que la del Pacífico central (donde habitan los individuos más viejos), a pesar del intenso esfuerzo de pesca realizado en esta última zona. 2) El coeficiente estimado de la mortalidad natural anual, de peces de más de 4 años de edad, en el Pacífico occidental, fue muy alto (2.5), pero la misma estimación en la que se incluyen los peces tanto del Pacífico central como del occidental, indican una estimación considerablemente inferior (1.2).

Joseph *et al.* (1964), supusieron que el aleta amarilla del Pacífico oriental (ARCAA) era independiente del que se encontraba más hacia el oeste, ya que los resultados de los experimentos de marcado y los estudios morfométricos expresan muy poca posibilidad de entremezcla en una dirección este-oeste, de esta especie. Sin embargo, expresaron cierta duda sobre el grado de independencia entre las zonas de bajura y de altura, debido a la distribución de captura aparentemente continua del atún aleta amarilla, pescado por palangreros japoneses al este de los 140°W.

Royce (1964), después de aplicar los análisis multivariados a las medidas morfométricas de la especie, declaró que "el desplazamiento este-oeste es limitado y la mayoría del aleta amarilla permanece a unos pocos cientos de millas de donde se encuentran cuando son juveniles". Sin embargo, como en el caso de Kamimura y Honma (1963), no pudo indicar ningún límite espacio-temporal de las subpoblaciones.

Se han realizado varios estudios sobre las subpoblaciones de esta especie, basados en métodos inmunológicos y bioquímicos (Suzuki (1952), Sprague (1967), Barrett y Tsuyuki (1967), Fujino y Kang (1968) y la IATTC (1971, 1972, 1973, 1974, 1975)). Sin embargo, no se puede, actualmente, llegar a ninguna conclusión general basados en estos estudios. Por ejemplo, los estudios de la transferina de Barrett y Tsuyuki (1967) y Fujino y Kang (1968), no indicaron ninguna heterogeneidad en el atún aleta amarilla muestreado en varios lugares del Pacífico oriental y en la región de las islas Line hawaianas (debido posiblemente al pequeño número de muestras y tamaño de las mismas). En comparación a éstos, los estudios actuales de la transferina indican heterogeneidad en el atún aleta amarilla en el Pacífico oriental (IATTC, 1971, 1972, 1973, 1974, 1975). Fujino (1970), al sumarizar los problemas en la metodología de esta clase de

estudio sobre los atunes, indicó que era necesario mejorar la calidad de las muestras (especialmente con respecto a la homogeneidad de la talla de los peces examinados) y perfeccionar las técnicas. Además, los estudios genéticos del atún aleta amarilla son fragmentarios (en el sentido de que el abarcamiento geográfico es bastante limitado) y se han realizado muy pocos estudios sistemáticos. Así que para aprovecharse de su gran valor discriminar directamente las subpoblaciones, es necesario ampliar las investigaciones.

Es probable que se hayan afectado considerablemente los estudios principales de la población del aleta amarilla por los fenómenos resultantes de ciertas características pesqueras. Por ejemplo, las hipótesis de Yabuta *et al.* (1958) y las de Kamimura y Honma (1963), pueden explicarse por la gran movilidad de la flota palangrera y por el aumento aparente del promedio de talla, del oeste al este, a lo largo del ecuador, de los peces capturados. Por otra parte, los resultados obtenidos por Joseph *et al.* (1964), sobre las existencias del Pacífico oriental pueden relacionarse, en parte, al hecho de que la pesca epipelágica ha manejado exclusivamente en el ARCAA durante el período de estudio.

METODOS

Los datos usados en este estudio no se basaron en observaciones directamente genéticas, pero más bien en otros datos biológicos y pesqueros como se ha hecho con otros estudios principales sobre la estructura de la población del aleta amarilla. En los siguientes párrafos discutiremos los problemas generales encontrados en un estudio de esta clase y los métodos para utilizar más eficazmente los datos que se tienen sobre la estructura de la población del aleta amarilla.

Hayase (1967), indicó en su análisis sobre el estudio de las subpoblaciones del aleta amarilla del Pacífico, que los investigadores habían seguido generalmente un patrón similar, comenzando con un estudio comparativo de alguna característica específica de esta especie, seguido luego por un estudio de varias otras características y finalmente un análisis comparativo de las etapas de desarrollo. Indicó que los problemas presentados en los tres estudios principales sobre este sujeto (Kamimura y Honma, 1963; Royce 1964 y Joseph *et al.*, 1964), podían solucionarse al examinar los resultados individuales en el contexto de las etapas de su ciclo vital. Hayasi pensó que mediante este método se podrían reconocer más fácilmente los errores sistemáticos (sesgo), inherentes en las pesquerías. Sin embargo, esto es difícil en cuanto al aleta amarilla, ya que esta especie presenta menos segregación típica dentro de su hábitat durante las diferentes etapas de desarrollo de su ciclo vital, que otras especies como el albacora, aleta azul y el aleta azul del sur (Honma y Hisada, 1971). En realidad, los datos palangreros de pesca (Kamimura y Honma, 1963) indican que la distribución del aleta amarilla es continua a lo largo del

ecuador, formando una estrecha banda y que la segregación por talla dentro de su habitat no se ha establecido claramente como lo ha sido con respecto a las tres especies antes mencionadas. Además, el aleta amarilla desova aproximadamente durante todo el año en esta región (Kikawa, 1966). A pesar de estos problemas, se adoptó este método en este estudio.

El otro problema más difícil es causado por las características (sesgo) en los datos que provienen en sí de la pesca. En las dos pesquerías principales que explotan el atún aleta amarilla, los palangreros capturan relativamente grandes individuos que nadan en las capas superficiales, mientras los cerqueros pescan cardúmenes superficiales que se encuentran formados generalmente por peces pequeños o grandes, depende de si están o no asociados con delfines. Además, comúnmente hablando, las buenas zonas pesqueras de aleta amarilla de los palangreros no son productivas para las pescas epipelágicas y viceversa. Por lo tanto es inevitable encontrar considerable error (sesgo) en los datos pesqueros y es necesario comparar cuidadosamente los datos obtenidos en las diferentes pescas. Para ayudar a resolver este problema, se debe prestar atención al hecho de que los peces pueden reaccionar differently con respecto a las mismas condiciones ambientales, dependiendo de su condición fisiológica y también de su etapa de desarrollo.

Madurez sexual y desove

Como parece que las variaciones en la zona y época de desove podrían servir para distinguir las subpoblaciones, empleamos estos factores en este estudio. La mayoría de los investigadores han utilizado el índice de las gónadas (índice que relaciona el peso del ovario a la talla del pez) para estudiar la madurez sexual de los atunes en el Océano Pacífico. Son especialmente interesantes los estudios de Orange (1961) sobre el aleta amarilla capturado por la pesca epipelágica del Océano oriental y los de Kikawa (1959, 1962 y 1966) correspondientes al aleta amarilla capturado por palangres en el Pacífico occidental y central.

En nuestro estudio hemos empleado también el índice de las gónadas. Nuestro material está formado principalmente por el aleta amarilla capturado con palangre. En algunos casos hemos comparado la madurez sexual de estos peces con la de aquellos capturados en la pesca epipelágica.

Índice gonádico del aleta amarilla capturado con palangre

Se obtuvieron datos de 58,258 atunes aleta amarilla capturados por barcos de investigación del Fisheries Agency of Japan y por barcos locales de las prefectura durante el período de 1970-1972. Estos últimos fueron barcos de investigación de las Estaciones Experimentales de Pesca y barcos de entrenamiento de las escuelas superiores de pesca.

El índice gonádico (IG) fue calculado en esta forma:

$$IG = \frac{P}{L^3} \times 10^4$$

en el que P es el peso en gramos de las gónadas de ambos lóbulos y L es la

longitud de horquilla en centímetros. Los índices se estratificaron por sexo, zonas de 5 grados, trimestres en el año y por tres grupos de talla (80-100 cm, 101-120 cm y más de 120 cm). Estos tres grupos de talla representan respectivamente peces inmaduros, intermedios y maduros, y se adoptaron basados en los estudios de madurez del aleta amarilla capturado por las artes palangreras (Yuen y June, 1957; Kikawa, 1966). Además, compilamos las tablas que indican la relación entre la talla de los peces y el índice gonádico.

En la Figura 3 se presenta la distribución geográfica del índice gonádico, por trimestre del año y grupos principales de talla, tanto de machos como de hembras de aleta amarilla. En general, el IG aumenta de acuerdo al incremento en la longitud del pez, y las pautas de los cambios zonales y estacionales del IG son independientes del sexo y de la clase de talla. Aparte de las zonas localizadas al este de los 110°W y de la región central del Pacífico sur (al sur de los 10°S), de las que se tienen muy pocos datos, las zonas principales de desove se encuentran entre los 15°N y 15°S. Las zonas de desove parecen extenderse hacia mayores latitudes en los alrededores de Hawái durante el verano septentrional y tan lejos al sur como los 25°S a lo largo de la costa oriental de Australia en el verano meridional.

Con el fin de descubrir el hecho del desove, Kikawa y Honma (1975) emplearon el índice de desviación (10 veces la diferencia entre la media sin ajustar del IG y el valor normal, considerando como normales los valores del IG, calculados solo por ejemplares en condiciones de inmadurez o reposo). Como hay poca diferencia en los índices normales de los diferentes grupos de talla del aleta amarilla del Pacífico, Kikawa y Honma calcularon finalmente un valor normal de 0.8 para todas los grupos de talla después de redondear el valor medio de 0.75 (Tabla 2). Luego se calcularon los índices de desviación para las mismas hembras de aleta amarilla que se emplearon en este estudio.

Se destacan dos grupos con índices de desviación relativamente altos (Figura 4), uno en el Pacífico occidental entre los 130°E y 170°E y el otro en el Pacífico central entre los 110°W y 160°W. El grupo occidental se localiza en el hemisferio meridional, mientras el central parece encontrarse principalmente al norte del ecuador. El máximo del desove parece ocurrir en los dos últimos trimestres en el Pacífico occidental y en el segundo y tercer trimestre en el Pacífico central. Sin embargo, el límite entre las dos zonas se vuelve algo impreciso en el tercer trimestre.

Este estudio corrobora las observaciones de las temporadas de desove de Marr (1948) y Shimada (1951), en el Pacífico occidental ecuatorial, de June (1953), Yuen y June (1957) en el Pacífico central, y de Kikawa (1966) en el Pacífico occidental y central.

Aunque no se ha encontrado una separación en la distribución geográfica del índice gonádico del aleta amarilla en el Pacífico oriental, basados en los datos de la pesca palangrera (Kume y Joseph, 1969; Shingu, Tomlinson y Peterson, 1974), en un estudio reciente (Knudsen, 1977) sobre

la madurez de atunes aleta amarilla capturados por embarcaciones cerqueras, indica que existe un desove intensivo en las zonas fuera del ARCAA, además de las zonas costeras de desove que ya se han descrito. Sin embargo, como los datos son escasos, especialmente a lo largo del límite del ARCAA, es necesario hacer más investigaciones para aclarar los detalles sobre el desove de esta especie en el Pacífico oriental.

Es interesante observar que los pequeños atunes aleta amarilla de 80-100 cm con altos índices de desviación, se encuentran en el trópico en zonas costeras o en aguas cercanas a las islas (Figura 4). Se han recibido datos sobre este fenómeno en las Islas Marshall (Marr, 1948), a la altura de las Islas Filipinas. (Bunag, 1956; referencia de Kikawa, 1966) a la altura de México central y Panamá (Orange, 1961) y en el Mar de Coral (Hisada, 1973). Sin embargo, este aleta amarilla aparentemente precoz, aparece también en la zona entre los 110°W y 140°W a lo largo de los 10°N en la zona central de desove donde virtualmente no existen islas. La relación entre la longitud de horquilla y el IG de la hembra del aleta amarilla se presenta gráficamente en la Figura 6, correspondiente a las zonas descritas en la Figura 5. De acuerdo a esta figura, las zonas principales de desove (Zonas 6 y 7 en el Pacífico occidental y la Zona 4 en el Pacífico central) se caracterizan por altos porcentajes de individuos con índices gonádicos de 2.1 o mayores (Kikawa, 1962) y (esporádicamente) índices gonádicos muy altos en las temporadas de desove.

Como generalmente la pesca palangrera y la cerquera no se encuentran en las mismas zonas, el único lugar donde es posible comparar simultáneamente los datos de ambas pescas es en la zona fuera del ARCAA, limitada por los 5°N - 10°N y 120°W - 145°W . Los datos palangreros consisten de 957 hembras obtenidas desde 1970 a 1972 y los datos cerqueros de 238 hembras obtenidas en 1970, 1972 y 1973.

Aunque no se tienen datos de aleta amarilla capturados por cerqueros en el primer trimestre, es evidente que el porcentaje con índices gonádicos de 2.1 o mayores en un grupo de una misma talla, es considerablemente más alto en todos los meses en los ejemplares capturados por artes cerqueras que en los obtenidos por las artes palangreras (Figura 7). Tanto los ejemplares cerqueros como palangreros presentan altos porcentajes de peces maduros de abril a septiembre con alguna pequeña diferencia entre los grupos de talla.

Hisada (1973) ha informado que existe una diferencia evidente en la madurez sexual del aleta amarilla muestreado por las artes palangreras y por las artes epipelágicas (línea de mano) en el Mar de Coral. Su raciocinio es que el atún aleta amarilla maduro asciende cerca a la superficie para desovar en aguas más cálidas (26°C y más altas) así que las artes pesqueras epipelágicas capturan selectivamente peces que se encuentran sexualmente maduros, mientras que las artes palangreras continúan capturando peces que son menos maduros en aguas más profundas y frías

(excepto durante el periodo en que la temperatura del agua asciende a más de 26°C a la profundidad de captura de las artes palangreras).

Para examinar la hipótesis de Hisada, se interpolaron los perfiles de la isoterma de 26°C a lo largo de los 5°N y 10°N en la zona bajo discusión, de acuerdo a los mapas de temperatura preparados por Robinson y Bauer (1971). Parece (Figura 8) que aproximadamente desde abril a agosto, la isoterma de 26°C se localiza por debajo de la profundidad mínima de los anzuelos palangreros (a unos 50 m (Hisada, 1973)), siendo así que esta isoterma se encuentra sobre los 50 m o desaparece completamente en otros meses. Por consiguiente, la hipótesis de Hisada puede aplicarse también en el caso actual, es decir, los peces que están desovando buscan temperaturas más cálidas que la de 26°C y estas temperaturas se encuentran a profundidades en las que los palangreros solo pescan aproximadamente de abril a agosto o septiembre. Sin embargo, es necesario hacer estudios detallados con datos más adecuados para determinar si la diferencia aparente de la madurez sexual del aleta amarilla pescado por las diferentes artes pesqueras permanece uniforme.

Distribución de larvas del aleta amarilla

El Japan Far Seas Fisheries Research Laboratory (FSFRL) ha compilado durante varios años datos sobre las larvas de atún y peces espada. Este estudio incluye las muestras de larvas obtenidas a bordo de 2 embarcaciones gubernamentales y 43 embarcaciones locales de la prefectura, durante 1956-1971, usando arrastres horizontales en la superficie, ya que este tipo de arrastre provee la mayor cantidad de muestras disponibles. A los datos del FSFRL se agregaron aquellos de los arrastres horizontales y superficiales del atún aleta amarilla del Pacífico oriental (Klawe, 1963, Tabla 2).

Como no hubo una diferencia importante en las capturas de las larvas de aleta amarilla en los arrastres horizontales y superficiales realizados de noche y durante el día (Ueyanagi, 1969), se combinaron estos dos tipos de datos para calcular la abundancia relativa de las larvas. Aunque la velocidad del arrastre de las redes se fijó en unos dos nudos, el diámetro de la red y el tiempo de arrastre cambiaron. Por consiguiente, se calcularon 1,012 m³ de agua filtrada como unidad de arrastre. Este volumen de agua equivale a la filtrada por una red con un diámetro de 1.4 m, con aproximadamente dos tercios de la apertura sumergida en el agua y arrastrada durante 15 minutos a 2 nudos. La cantidad de larvas por unidad de arrastre fue calculada por zonas de 5 grados y por trimestre, sin considerar el año.

Existen tres zonas principales en el Pacífico ecuatorial con alta densidad de larvas de aleta amarilla: la zona occidental (130°E-170°E), la zona central (130°W-160°W) y la zona oriental (al este de los 110°W) (Figura 9). En el verano septentrional, el desove de esta especie ocurre tan lejos al norte como los 35°N a lo largo de la costa japonesa del

Pacífico en la Corriente de Kuroshio y tan lejos al norte como los 30°N, adyacente al Hawái. La Figura 9 presenta también las subdivisiones del Pacífico, que empleamos al examinar los cambios estacionales en la densidad de las larvas. Estas subdivisiones incluyen prácticamente todas las zonas del Océano Pacífico en donde la temperatura superficial es superior a 26°C durante todo el año o parte de éste (Ueyanagi, 1969). El promedio de la densidad trimestral de las larvas se calculó solo por zonas de 5 grados en las que se realizaron cinco o más arrastres (círculos negros en la Figura 9).

Los máximos estacionales de la densidad de larvas aparecen en el segundo trimestre en la 1 Zona, en el cuarto trimestre en la 2 y 3 Zona, en el tercer trimestre en la 4 Zona y en el segundo trimestre en la 5 Zona (Figura 10). Aunque no se obtuvieron datos en el tercer trimestre en la 6 Zona, parece que existe un máximo en el segundo trimestre. No se encontró en ninguna de las zonas máximos de densidad de larvas en el primer trimestre.

Estos resultados coinciden bastante bien con los estudios anteriores del desove de esta especie (Matsumoto, 1958; Orange, 1961; Klawe, 1963; Kikawa 1966 y Ueyanagi, 1969). Sin embargo, parece que existan por lo menos dos diferencias. La comparación de los máximos estacionales de desove presentados en nuestro estudio y aquella presentada en el estudio de las gónadas de Kikawa (1966) (véase Figura 38 de Kikawa), indican que existe un período de desfasamiento en la ocurrencia de los máximos de desove, debido probablemente al orden secuencial del fenómeno. Es decir, el máximo estimado por el estudio de las gónadas precede generalmente aquel calculado según las muestras de las larvas. Por ejemplo, en la 2 Zona la densidad de las larvas alcanza un máximo en el cuarto trimestre, mientras que el estudio de las gónadas parece indicar que el desove es superior en el tercer trimestre. Otra diferencia es que las estimaciones del potencial de desove por medio de los IG de Kikawa (1966) en el Pacífico occidental ecuatorial fueron bajas en contraste con las zonas ecuatoriales central y oriental, mientras no parece que exista una diferencia apreciable en la relativa abundancia de las larvas a lo largo de la zona ecuatorial, por lo menos entre el Pacífico occidental ecuatorial y el central (Figura 9). La causa de esta última diferencia no es evidente. Sin embargo, Kikawa (1966), indica tres causas posibles de error (sesgo) incluidas en la estimación de su índice de desove (K). Dos de estas causas (omisiones en el abarcamiento geográfico de los datos del IG y la selección posiblemente de un año anómalo en la estimación de la abundancia de los peces) no parecen lo suficientemente serias para cambiar el dominio relativo de K entre las dos zonas mencionadas. Sin embargo, la posible subestimación del potencial de desove del aleta amarilla más pequeño y precoz, indicado por Kikawa y mencionado también anteriormente, merece estudiarse aún más. En el pasado, se creía que los peces de menos de 120 cm (que forman una parte importante en la captura palangrera del Pacífico

occidental) eran demasiado pequeños para desovar. Es interesante observar que los ejemplares del aleta amarilla del Pacífico occidental y central con huevos maduros a punto de desovar informados por Kikawa (1966), se localizaron aproximadamente en las zonas de alta densidad de larvas examinadas en este estudio.

Los arrastres horizontales y superficiales indicaron mayores concentraciones de larvas de aleta amarilla en el Pacífico noreste que en el Pacífico occidental o central (Figura 10). Aunque se obtuvieron larvas de esta especie hasta profundidades de 300 m (Matsumoto, 1958), se considera que la mayoría de las larvas aparece encima de la termoclina (Klawe, 1963). Sin embargo, aún en zonas en las que la termoclina es bastante profunda, tratan de congregarse en los primeros 50 m de la superficie (Matsumoto, 1958). En el Pacífico noreste se localiza la termoclina a profundidades extremadamente bajas (en promedio, a unos 30 m en las localidades del muestreo de larvas, de Klawe). Así, que es posible que la alta concentración de larvas de aleta amarillo en el Pacífico noreste, se deba a una termoclina inusitadamente superficial (ejemplo, la termoclina sirve para concentrar las larvas). En otras palabras, este estudio, basado en arrastres horizontales superficiales, puede subestimar la abundancia relativa de las larvas en el Pacífico occidental y central.

Distribución

Se examina en esta sección, la distribución geográfica de la captura del aleta amarilla, usando los datos de la pesca palangrera japonesa que maniobra en casi todo el Pacífico tropical y los de la pesca epipelágica (cerqueros y barcos de carnada) que maniobran en el Pacífico oriental. Se examina también brevemente la distribución vertical de la especie junto con los resultados de estudios anteriores.

Distribución del aleta amarilla capturado por la pesca palangrera japonesa

Se calculó el promedio de los índices de captura (número capturado de atunes aleta amarilla por 100 anzuelos) por mes y zona de 1 grado durante el período de 1967-1972, como un índice de la abundancia relativa del aleta amarilla disponible a las artes palangreras.

En la Figura 11 se presenta la distribución del promedio de la proporción de la captura mensual. Se observará, por lo general, que las zonas con altas proporciones de captura se encuentran localizadas a lo largo del ecuador, encontrándose las más altas en las zonas ecuatoriales occidentales y reduciéndose gradualmente hacia el este. Al este de los 140°W, aparecen dos zonas de captura más alta al norte y sur del ecuador en el primero y segundo semestre del año, respectivamente. Las proporciones de captura en las zonas costeras del Pacífico oriental son muy bajas, excepto en el primer semestre del año aproximadamente a los 10°N.

Los cambios estacionales en la proporciones de captura por anzuelo

de las tres principales regiones de pesca palangrera se describen brevemente en la forma siguiente:

1) Región ecuatorial central occidental — Se define como la zona entre los 5°N y 10°S y al oeste de los 140°W. Sin embargo, se reduce a una zona entre los 5°N y 5°S al oeste de los 180°W. Existen muy pocos cambios estacionales en la distribución de las proporciones de captura en esta región, con excepción de que las proporciones entre los 170°E y 140°W se reducen de agosto a diciembre. Desde la parte occidental de esta región se obtienen capturas moderadamente altas extendiéndose a lo largo de la Corriente de Kuroshio y virando a lo largo de la Corriente Oriental Australiana de acuerdo a la fuerza estacional de estas corrientes, aunque se encuentran durante casi todo el año algunos parches locales con alta proporción de captura a la altura de Sydney (Australia).

2) Región nordeste — Esta es una zona localizada entre los 5°N y 10°N y al este de los 140°W. Se encuentran dos sectores zonales con altas proporciones de captura en esta región. El sector occidental localizado entre los 130°W y los 140°W, tuvo altas proporciones de captura de abril a julio. Por otra parte, el sector oriental, que aparece a lo largo de los 10°N y entre los 85°W y 110°W, tuvo altas capturas de diciembre a junio, sin embargo, el esfuerzo fue escaso en esta zona durante otros meses.

3) Región sudeste — Es una zona que se encuentra al este de los 140°W localizada cerca al ecuador en la parte occidental, extendiéndose diagonalmente tan lejos al sur como al sudeste de los 20°S en su extremo oriental. La zona con proporciones más altas de captura se encuentra en la parte oriental de esta región entre los 85°W y 95°W. Parece que la zona con proporciones más altas de captura cambia su posición hacia el sur de julio a octubre.

Nuestro estudio sobre la distribución de las proporciones de captura por anzuelo del atún aleta amarilla indicó que existía, posiblemente, una separación entre los 110°W y 120°W. Esta separación puede verse también en el estudio de Shingu *et al.* (1974), quienes usaron en su mayor parte los mismos datos empleados en este estudio. Sin embargo, como se mencionó anteriormente, Joseph *et al.* (1964), basados en los datos de abril de 1962 a mayo de 1963, no encontraron ninguna separación en la distribución de las estadísticas japonesas palangreras, correspondientes a la zona situada al este de los 140°W. Kume y Joseph (1969) tampoco pudieron indicar separaciones en datos similares de 1964 a 1966. Parece que esta discrepancia se debió relativamente en su mayoría al establecimiento de una nueva zona costera por la pesquería palangrera en la región nordeste a lo largo de los 10°N. Aunque la flota palangrera abarcó casi todo el Pacífico tropical en la primera mitad de la década de los sesenta, esta nueva región no se explotó sino en la segunda mitad de esa década.

Distribución del aleta amarilla capturado por la pesca epipelágica en el Pacífico oriental

Se han hecho varios estudios sobre la distribución del aleta amarilla capturado por embarcaciones de carnada en el Pacífico oriental durante el período en el que la pesca con carnada era el método principal de la pesca epipelágica (Griffiths, 1960; Blackburn y asociados, 1962; Broadhead y Barrett, 1964). Como esa pesca fue reemplazada en su mayor parte por la pesca con redes de cerco a principios de los años sesenta y está maniobrando actualmente solo en pequeña escala en las zonas costeras y en la vecindad de los bancos e islas, se examinaron solo superficialmente los datos actuales de las embarcaciones de carnada.

En contraste a los palangreros que maniobran continuamente durante todo el año sobre extensas zonas, incluso aún zonas de poca abundancia de aleta amarilla, la distribución del esfuerzo de pesca de los cerqueros en el Pacífico oriental ocurre de una manera tan descontinua (especialmente desde que se iniciaron las reglamentaciones de pesca del aleta amarilla en 1966), que es difícil obtener una representación real de la distribución del aleta amarilla disponible a la pesca. La distribución de la captura y de la captura por día normal de pesca no parece que sea muy diferente en los viajes sin reglamentar excepto en aquellas zonas marginales en donde hubo poco esfuerzo (Figura 12). Por consiguiente, los cambios zonales y estacionales en las zonas en las que las embarcaciones con cerco han pescado, como se describen aquí, se basan solamente en la distribución de la captura del aleta amarilla de viajes sin reglamentar en los que se capturó principalmente esta especie (Figura 13).

Las regiones cerqueras de pesca, en el primer trimestre, abarcan casi toda el ARCAA al norte del ecuador, (sin embargo, recientemente, la pesca del aleta amarilla se ha extendido a zonas tan lejanas como al sur de los 10°S). Se obtuvieron buenas capturas frente a la parte central y sur de México, a la altura de Costa Rica y en la vecindad del Golfo de Guayaquil. Durante los años que abarcan este estudio (1965-1973) la captura de aleta amarilla obtenida por cerqueros en el *Panama Bight* fue pobre excepto en 1973.

En el segundo trimestre, las zonas buenas de pesca en el ARCAA fueron aproximadamente iguales a las del primer trimestre, excepto que se extendieron al norte, frente a la costa del sur de Baja California.

Desde 1967, debido a las reglamentaciones, la captura en el tercer trimestre ha provenido principalmente de la parte exterior del ARCAA. La mayor parte de la pesca en esta zona, ocurre a lo largo de los 10°N, tan lejos al oeste como los 145°W. En el ARCAA, parece que se captura aleta amarilla a la altura del sur de Baja California y frente a la parte meridional de México, aunque no se consiguieron casi datos para el tercer trimestre, excepto en 1965.

La captura fuera del ARCAA a lo largo de los 10°N parece ser en el cuarto trimestre algo inferior a la del tercer trimestre. Se recibieron

informes de buenas capturas en las zonas a lo largo de los 5°N, justamente fuera del ARCAA y a lo largo de los 3°N (límite norte de una de las zonas experimentales de pesca que se abrió a la pesca en 1973 (IATTC, 1974)). Parece que hubo pesca en el ARCAA a lo largo de los 10°N desde la zona costera hasta más lejos mar adentro.

A través de los años de este estudio, no ha habido virtualmente esfuerzo de pesca precisamente al este del límite del ARCAA. Por consiguiente, se puede colegir muy poco sobre si el aleta amarilla es accesible a la pesca epipelágica en esta zona. Parece que aquí no existen barreras ambientales en la captura de esta especie.

Distribución vertical del aleta amarilla

Se conoce muy poco sobre la distribución vertical del aleta amarilla debido a la falta de un método adecuado de reconocimiento. Sin embargo, se ha tratado de obtener más conocimiento mediante el estudio del contenido estomacal (Watanabe, 1958) y la profundidad de captura palangrera (Watanabe, 1961).

El desarrollo reciente en el Pacífico occidental de un nuevo método palangrero de pesca (designado para capturar patudo) en el que se fijan los anzuelos a mucha más profundidad que lo ordinario, ha suministrado nueva información sobre la distribución vertical del aleta amarilla. El promedio máximo de profundidad de un palangre ordinario es de unos 100 m (Honda, 1966) mientras que la línea del nuevo palangre (Kamijo, 1962) es de unos 200 m o más de profundidad.

La proporción de captura del aleta amarilla capturado con palangres de profundidad normal o más profundidad en diferentes zonas se presenta en la Figura 14. Estos datos parecen indicar que las proporciones de captura de aleta amarilla calculadas para estos dos métodos de pesca no se diferencian demasiado. Para confirmar esta observación, la media de las proporciones de captura del aleta amarilla fue probada estadísticamente por los dos métodos palangreros. Como las proporciones de captura cambian muy rápidamente con la latitud en esta región, se hizo la prueba usando datos de latitudes en las que se emplean simultáneamente los dos métodos de pesca (ejemplo dado, la prueba de la diferencia de las medias en valores pares). Una prueba bilateral ($\alpha = 0.05$) indicó que la media de las diferencias en la proporción de captura de los dos métodos no se diferenciaba de cero ($t_0 = 1.00$, g.l. = 33). Así que el aleta amarilla se captura más o menos igualmente a todas las profundidades. Sin embargo, es necesario cierta discreción, ya que no se tiene seguridad a qué profundidades los peces son actualmente capturados. Por ejemplo, en lances profundos, los peces pueden pescarse a menos profundidad mientras los anzuelos se están hundiendo o se están halando.

Un estudio más reciente (Suzuki, *et al.*, 1977) sobre datos similares, le da más importancia a las comparaciones espacio-temporales y a la influencia de la profundidad de la termoclinia. Estos autores concluyeron

que los palangres regulares pueden capturar más peces que los palangres más profundos, especialmente cuando la termoclina se encuentra por encima de la profundidad media a la que pescan los palangres más profundos. No parece que ninguno de estos tipos de palangre sea útil en determinar la profundidad máxima del aleta amarilla o aún una profundidad menor en donde la densidad disminuye significativamente.

Relación entre las condiciones ambientales y la distribución del atún aleta amarilla capturado por embarcaciones palangreras

Entre los varios estudios sobre la relación que existe entre la distribución del aleta amarilla y las condiciones ambientales, debe citarse aquí debido a su generalidad, la hipótesis de Nakamura (1965) que trata de la segregación intraespecífica, interespecífica o de las dos en el habitat de los atunes y peces espada en las corrientes oceánicas. Sin embargo, su hipótesis fue concebida principalmente por los estudios de la pesca palangrera en el Pacífico occidental y por consiguiente, se han observado algunos problemas al aplicar la hipótesis en otras zonas (Suda *et al.*, 1969; Yamamoto *et al.*, 1969). Kawai (1969) y Suda *et al.* (1969) quienes volvieron a examinar la hipótesis de Nakamura y una idea similar de Yanakawa *et al.* (1969), indicaron que la estructura vertical térmica (especialmente la topografía de la termoclina) es un factor importante en la aproximación de la distribución de los atunes. Se observa que la topografía de la termoclina se aproxima también a otras características hidrográficas.

Basado en el estudio de la pesca palangrera del Atlántico, Kawai (1969) propuso que las regiones principales de pesca de aleta amarilla en el Atlántico se caracterizaban por dos condiciones: (1) la temperatura de la capa mixta de la superficie (o simplemente la temperatura superficial) es alta ($\geq 27^{\circ}\text{C}$) y (2) la capa mixta es bastante delgada (las islas que se encuentran en las vecindades o zonas con abundante alimento para los atunes pueden substituirse con respecto a esta segunda condición). Es interesante observar como la hipótesis de Kawai se aplica al aleta amarilla del Pacífico. En aquellas zonas del Pacífico central y occidental en las que se encuentra la primera condición, hay generalmente una correlación positiva entre la presencia de las islas y las altas proporciones de captura, pero se encuentran muchas regiones en mar abierto con altas proporciones que tienen una capa mixta gruesa superior. Desafortunadamente, no se tienen datos sobre la abundancia del alimento para el aleta amarilla. Se examinó más cuidadosamente el Pacífico oriental ya que ahí se encuentran menos islas y relativamente fuertes cambios estacionales y zonales en esta región tanto de la temperatura superficial como del grosor de la capa mixta. Se emplearon los mapas mensuales de la temperatura superficial y de la profundidad de la termoclina preparados por Wyrtki (1964). Kawai no definió lo que quería decir por una termoclina de poca profundidad, así que se escogieron arbitrariamente 50 m como la profundidad máxima. La Figura 15 presenta esquemáticamente la reciprocidad, por

meses, entre las zonas favorables de captura de aleta amarilla por las artes palangreras y la distribución de las altas proporciones de captura (≥ 1.51 como en la Figura 11). Es evidente la poca relación que existe entre la presencia de zonas favorables, como lo define Kawai (1969) y las altas proporciones de captura de aleta amarilla, especialmente durante el segundo semestre del año.

Es digno de mencionarse que la pesca palangrera a la altura del Perú obtiene cantidades substanciales de aleta amarilla, que se considera como reproductivamente inactivo o en condiciones de reposo (Kume y Joseph, 1969; Shingu *et al.*, 1974). Esto parece demostrar la posibilidad de usar las etapas de desarrollo de las gónadas para ayudar a explicar más detalladamente la distribución de las especies.

Cambios en los índices de densidad del aleta amarilla capturado por embarcaciones palangreras japonesas

Kamimura *et al.* (1966) y Honma *et al.* (1971), indicaron que las proporciones de captura por anzuelo de la flota japonesa palangrera en el Pacífico occidental al oeste de los 180° no mostraban reducción, por lo menos en el período en el que se inició la pesca a fines de la década de los años cuarenta hasta 1960, mientras que en el Pacífico central oriental al este de los 180° , se indicó una reducción evidente desde el principio de la pesquería. Como se mencionó anteriormente, se determinó que la falta de reducción en los índices de densidad del Pacífico occidental se debe al reclutamiento de pequeños peces en la pesca palangrera de esa región; sin embargo, a medida que los peces crecen y se desplazan al este, se encuentran expuestos sucesivamente a una explotación mayor en el Pacífico central y oriental, produciéndose así una reducción en la zona central.

Al agregar datos recientes y al usar subdivisiones más pequeñas de zonas pesqueras principales (Figura 16), se calculó el promedio de los índices de densidad anual como sigue:

$$\hat{d} = \frac{1}{m} \sum_{i=1}^m \left(\frac{N_i}{A_i} \right) = \frac{1}{m} \sum_{i=1}^m \left(\frac{\sum_{j=1}^n \frac{(C_{ij} A_{ij})}{g_{ij}}}{\sum_{j=1}^n (A_{ij})} \right)$$

donde \hat{d} = índice del promedio de la densidad anual en una zona principal y particular de pesca en un año especial.

m = número de trimestres en los que se realizó la pesca

N_i = índice de la magnitud de la existencia en el i^{avo} trimestre

A_i = extensión de la zona pesquera durante el i^{avo} trimestre

C_{ij} = captura en número de la unidad zonal j^{ava} de 5 grados de la región principal de pesca en el i^{avo} trimestre

g_{ij} = esfuerzo nominal en términos de lance por número de anzuelos en la unidad zonal j^{ava} de 5 grados de la región principal de pesca en el i^{avo} trimestre

A_{ij} = índice relativo de la zona en la unidad zonal j^{ava} de 5 grados (Honma *et al.*, 1971) en el i^{avo} trimestre.

En este estudio no se observa tan claramente la diferencia aparente en la tendencia descendente de los índices de densidad entre el Pacífico occidental y el central oriental, indicada por estudios anteriores (Figura 17). Parece que la agregación de datos más recientes ha disminuido la diferencia entre las dos regiones. Hay que destacar que las tendencias descendentes de los índices de densidad en las zonas E_1 , E_2 y E_3 , las regiones principales palangreras de pesca en el Pacífico occidental se asemejan mucho las unas a las otras.

Composición de talla del aleta amarilla capturado por embarcaciones palangreras

Se utilizaron solo los datos de los palangreros japoneses ya que no se tenían datos adecuados de las pescas palangreras taiwanesas y sudcoreanas. Empleamos la captura en cantidades de peces para el período de 1966-1972, tabulándola por trimestres, zonas de 5° de latitud por 10° de longitud e intervalos de talla de 2 cm. Las muestras frecuencia-talla fueron ponderadas por la cantidad correspondiente de captura, conforme los datos obtenidos por el Japan Fisheries Agency (1968-1974) para estimar la composición de talla de la captura en cada zona de $5^{\circ} \times 10^{\circ}$.

Los datos estimados por trimestres de la composición de talla se agruparon según tres zonas principales, norte ($10^{\circ}\text{N}-25^{\circ}\text{N}$), central ($10^{\circ}\text{N}-5^{\circ}\text{S}$) y sur ($5^{\circ}\text{S}-25^{\circ}\text{S}$) y se indican por intervalos de 10° de longitud en todas las zonas al este de los 130°E (Table 1 del Anexo). En esta tabla, la zona de los 130°E , por ejemplo, señala la zona de los 130°E a los 140°E , mientras que la zona de los 130°W , indica la zona de los 130°W a los 140°W . Se combinaron todas las zonas de 10° , al oeste de los 120°W , hasta la línea de la costa y ésto se indica en la Tabla 1 del Anexo por el signo $<110^{\circ}\text{W}$. Con respecto a la composición de talla de los peces de estas tres zonas principales, se combinaron los datos de los años de 1966-1972, por zonas principales e intervalos de 10° de longitud (Figura 18). Además se combinaron los datos para luego presentarlos por seis zonas principales (Figura 19).

Aunque existen variaciones anuales en los patrones zonales de la composición de talla, puede observarse que existe una tendencia constante en la que los individuos más grandes llegan a ser cada vez más dominantes en la pesca del ñoste al este en las tres zonas principales (Figura 18). Sin embargo, en las zonas al este de los 110°W , los peces pequeños de menos de 100 cm aparecen, a veces, en cantidades apreciables. Entre paréntesis, la moda prominente, de unos 100 cm, en la zona meridional al este de los 110°W , en el tercer trimestre (Figura 18), se debe casi en su totalidad a la captura de 1972 (Tabla 1 del Anexo). En las regiones norte y sur, por lo

general, dominan más los grandes peces, que en la región intermedia en zonas de la misma longitud, excepto en las zonas al este de los 130°W (Figura 19).

Este estudio confirma un cambio progresivo longitudinal en la composición de talla del aleta amarilla capturado por artes palangreras, según ha sido informado por Yabuta, *et al.* (1958) y por Kamimura y Honma (1963). Sin embargo, vale la pena señalar que los peces pequeños de una talla que fluctúa de 80 a 100 cm, abundantes en la captura del Pacífico occidental, pero más bien raros en el Pacífico central y oriental, se encuentran en cantidades apreciables en algunos años en la captura de las zonas al este de los 160°W (Tabla 1 del Anexo). Su aparición en el Pacífico central y oriental no parece que haya sido mencionada por Yabuta *et al.* (1958) o Kamimura y Honma (1963), debido probablemente a las siguientes razones. En el primer estudio, la pesca palangrera no había maniobrado aún en completa escala en el Pacífico central y absolutamente nada en el Pacífico oriental y las muestras del Pacífico central eran pocas obteniéndose en su mayoría en el cuarto trimestre, en el que dominaban los aleta amarilla más grandes (Figura 18). En el otro estudio, la composición de talla fue calculada por trimestres, pero las muestras se sumaron a través de los años. Como no aparecieron peces pequeños en las muestras en cada año y su cantidad con relación a la captura total no fue grande, la combinación de los datos de varios años debe reducir su cantidad relativa en la composición de talla. En realidad, cuando se calculan los datos por trimestre, combinando los años, como en la Figura 18, los peces pequeños del Pacífico central y oriental se indican solamente como una pequeña fracción en la composición de talla (excepto en la zona meridional al este de los 120°W, en el tercer trimestre, como se mencionó anteriormente). No es posible interpretar estas capturas de pequeños aleta amarilla como si se relacionaran a la proximidad de las islas (en donde comúnmente se congregan los peces pequeños), ya que la zona al norte de los 5°S y al este de los 150°W, no tiene virtualmente islas. Además, como se mencionará más tarde, las flotas cerqueras en el Pacífico oriental que maniobran en las zonas de altura entre los 120°W y 150°W a lo largo de los 10°W, capturan cantidades substanciales de peces de pequeña talla como también de tallas más grandes. Por consiguiente, su aparición ocasional en la composición de talla palangrera en aquellas zonas, no debe considerarse solamente como una desviación (sesgo) del muestreo.

Composición de talla del aleta amarilla capturado por cerqueros en el Pacífico oriental

Las composiciones de talla en las capturas de aleta amarilla en términos de peso, obtenidas por la flota cerquera en el Pacífico oriental, fueron calculadas para el ARCAA y fuera de esta zona, durante el período de 1966 a 1972 y de 1969 a 1974, respectivamente. Se emplearon las frecuencias de peso en lugar de las frecuencias numéricas para obtener

modas de una medida más similar. Esto debe tener muy poco efecto en las posiciones modales. Se combinaron estas composiciones frecuencia-talla a través de los años y se agruparon por trimestres y zonas principales de pesca (Figura 20), en las que la composición de talla es generalmente similar. Existe una tendencia en el ARCAA, y en menor grado fuera de esta zona, en la que los grandes peces llegan a dominar desde las zonas costeras a las oceánicas (Figura 21). Sin embargo, el gradiente de esta tendencia, en términos de la distancia desde la costa, no parece ser el mismo en diferentes zonas latitudinales. Es decir, en las zonas N₂ (10°N-20°N) y N₃ (0°-10N) se capturan atunes aleta amarilla de más de 120 cm en cantidades substanciales cerca a la costa (ejemplo dado, en la Figura 20, zonas 3, 4 y 10), mientras que tales peces rara vez aparecen en las zonas costeras adyacentes a las zonas N₁ (20°N-35°N) y S (0°-20°S) excepto en las zonas 18 y 19, en el primer trimestre.

Debe observarse en las composiciones de talla fuera del ARCAA que además de los peces grandes, dominantes, se capturan en el tercer trimestre peces pequeños de menos de 80 cm, en cantidades relativamente grandes. Obsérvese especialmente la aparición de pequeños peces que fluctúan entre 40 y 60 cm en el tercer trimestre en la zona 16. Sin embargo, existe la posibilidad de que hayan recibido informes incorrectos sobre la zona de captura de algunos de estos peces pequeños. La talla de los peces capturados más lejos mar afuera (zona 17) parece ser predominantemente grande, aunque se tienen pocos datos.

DISCUSION

Como se observó anteriormente, nuestro estudio sobre la abundancia relativa de las larvas de aleta amarilla indica, aparentemente, tres zonas de gran densidad (Pacífico occidental, central y oriental). Los análisis de la madurez sexual basados en los índices de las góndolas del aleta amarilla muestreado en las pescas palangreras y cerqueras, indican también un desove intensivo en esas tres zonas. Sin embargo, excepto por la distribución de los índices de la captura palangrera que muestra una separación aparente, que corresponde aproximadamente a aquella que existe entre la zona central y la oriental antes mencionada, no se obtuvieron resultados de las investigaciones de los datos de talla o de los datos de la captura y el esfuerzo, ya sea de las pescas palangreras o epipelágicas, que indiquen que existan subpoblaciones o existencias aisladas de atún aleta amarilla.

En el siguiente análisis, se comparan y se relacionan recíprocamente los resultados de las diferentes observaciones.

La inclinación este-oeste observada en los datos palangreros de la composición de talla

El aumento progresivo en la talla del aleta amarilla capturado por embarcaciones palangreras del oeste al este, a lo largo del ecuador, es un fenómeno consistente, aparte de la aparición ocasional de pequeños peces

en el Pacífico central y oriental. Esta inclinación ha desempeñado un papel importante en los estudios del aleta amarilla del Pacífico, y el fenómeno ha sido en realidad intrepretado de dos maneras diferentes. Una es que el aleta amarilla se desplaza del Pacífico occidental (aguas costeras) al Pacífico central (alta mar) a medida que crecen, Kamimura y Honma (1963). La otra, basada en un estudio morfométrico (Royce, 1964) le da una importancia limitada al desplazamiento de la especie. Este segundo modelo indica que la inclinación se debe a la selectividad diferencial de las artes palangreras en cuanto a la talla de los peces en relación a la profundidad de la termoclina (Suda y Schaefer, 1965). Se basa sobre la hipótesis de que el aleta amarilla habita principalmente la parte superior de la capa mixta y que la mayoría de los peces más grandes de esta especie viven en la parte más profunda de la capa mixta (cerca a la cima de la termoclina) así que los anzuelos palangreros fijados aproximadamente a una medida constante de profundidad, llegan gradualmente a ser más eficaces en la captura de grandes individuos desde el Pacífico occidental al oriental, a medida que la capa mixta superior pierde profundidad hacia el este. Según la información sobre la distribución vertical, de la sección anterior, la hipótesis de Suda y Schaefer (1965) de que el atún aleta amarilla vive principalmente sobre la termoclina, puede considerarse admisible. Sin embargo, es difícil encontrar información para confirmar la validez de su segunda hipótesis sobre la segregación vertical del habitat, según la talla de los peces.

Como las artes palangreras generalmente no capturan en el Pacífico oriental cantidades substancialmente más grandes de pequeños peces aleta amarilla (80 cm a 100 cm) que en el Pacífico occidental a pesar de la abundancia más alta de esta clase de talla en el Pacífico oriental, se puede afirmar que la selectividad de talla de las artes palangreras cambia con respecto a la zona.

La comparación de las regiones pesqueras de las artes palangreras y cerqueras correspondientes al atún aleta amarilla en el Pacífico indica una relación inversa. Las principales regiones de pesca de las artes palangreras se sitúan en el Pacífico occidental y central tropical, pero solo en una zona limitada del Pacífico oriental, siendo que lo contrario es evidente respecto a las regiones cerqueras de pesca. En la época en que Suda y Schaefer (1965) compararon los datos de la composición de talla, esta relación fue característica, es decir, estas dos artes muy rara vez maniobraban en las mismas zonas. Este no es más el caso, así que decidimos comparar los datos de la composición de talla de las dos pesquerías por estratos espaciotemporales, en los que las dos pescas maniobraban simultáneamente.

Se escogieron los datos de la composición de talla de las dos pesquerías, obtenidos en las mismas zonas de $5^{\circ} \times 10^{\circ}$, en los mismos meses de los mismos años. Se tenían datos de 16 estratos de zonas y meses en el ARCAA para 1967-1969 y para 13 estratos de zonas y meses fuera del ARCAA para 1969-1971, (Figura 22). Se sigue indicando la selectividad diferencial de las artes palangreras respecto a los grandes atunes aleta amarilla, aunque

parece que en estos datos son menores las diferencias en la composición de talla de las dos pesquerías que en los de Suda y Schaefer (1965, Fig. 14). A propósito, existe alguna duda sobre la información de que los peces de menos de 75 cm capturados por cerqueros fuera del ARCAA, fueron actualmente capturados allí.

A pesar de la falta de una evidencia directa sobre la segregación vertical, por talla, de los peces, la explicación de Suda y Schaefer de la inclinación este-oeste en la longitud de los peces capturados por artes palangreras, parece razonable en cuanto al Pacífico central y oriental, donde se marca especialmente el gradiente de la profundidad de la termoclina en una dirección este-oeste. Sin embargo, no parece que esta explicación pueda aplicarse al Pacífico occidental, ya que el espesor allí de la capa mixta, apenas cambia en una dirección este-oeste entre aproximadamente los 130°E y 180°; en realidad puede llegar a ser aún más profunda del oeste al este en esta zona (Figura 23). No obstante, la composición de talla del aleta amarilla capturado por las artes palangreras en la zona occidental indica un aumento en la porción de los grandes peces hacia el este. Además, no se indica que el aleta amarilla capturado en el Pacífico ecuatorial occidental con palangres profundos sea apreciablemente más grande que aquel capturado con palangres normales (Yukio Warashina, comunicación personal).

Por lo tanto, el grado de desplazamiento de los aleta amarilla es de gran importancia al examinar las diferentes interpretaciones de la inclinación observada en los datos de la composición de talla de la pesca palangrera. Sin embargo, antes de discutir el grado de desplazamiento, se examinarán brevemente los cambios costeros-oceánicos de la composición de talla del aleta amarilla capturado por las artes cerqueras en el Pacífico oriental.

Composición de talla del aleta amarilla capturado por flotas cerqueras en el Pacífico oriental

Según las muestras de captura del aleta amarilla obtenido por cerqueros en el Pacífico oriental, se observó un aumento en las proporciones de grandes individuos, de las zonas costeras a las de altura (este a oeste), aunque no tan definido como en las capturas palangreras. Se han dado dos hipótesis (IATTC, 1976) para explicar esta tendencia: 1) el desplazamiento hacia alta mar del aleta amarilla a medida que crece y 2) la selectividad de talla en la pesca. Los análisis recientes de los datos del mercado indican que la segunda hipótesis es la más razonable (IATTC, 1977).

Se puede emplear la segunda hipótesis para explicar la tendencia costera-oceánica en la siguiente forma. Se conoce que el aleta amarilla en asociación con delfines capturado con redes de cerco, es generalmente más grande que el capturado por otros métodos. Además, la mayoría de las capturas de cardúmenes que no están asociados con delfines se obtienen en las zonas de bajura, mientras que las capturas de cardúmenes asociados con delfines forman la mayor parte de la captura oceánica. Esta situación

debe contribuir significativamente al gradiente longitudinal en las muestras de talla obtenidas por la pesca cerquera. Sin embargo, como tanto los cerqueros como los palangreros capturan selectivamente grandes atunes aleta amarilla en las zonas oceánicas, parece que no existe actualmente un método efectivo para examinar la abundancia de los peces pequeños de menos de 80 cm. Así que no se sabe con certeza si la segunda hipótesis es la correcta.

Grado de desplazamiento

Durante varios años se han realizado experimentos de marcado del atún aleta amarilla explotado por la pesca epipelágica en el Pacífico oriental. Los análisis de los datos de los peces recapturados hasta 1965, indican que el atún aleta amarilla realiza grandes desplazamientos a lo largo de las regiones costeras en el ARCAA (Fink y Bayliff, 1970). Sin embargo, el grado de desplazamiento costero-oceánico (este-oeste) no fue revelado por estos experimentos, porque hasta mediados de la década de los sesenta, la flota epipelágica solo había pescado cerca a las zonas costeras y en algunas pocas islas mar afuera. Sin embargo, como los palangreros japoneses que estaban maniobrando en las zonas oceánicas, adyacentes y parcialmente sobreponiéndose a las zonas pesqueras epipelágicas, no habían obtenido recapturas de marcas fuera del ARCAA, se supuso que no había un desplazamiento en gran escala costero-oceánico (Schaefer, *et al.*, 1961; Joseph *et al.*, 1964).

Los resultados de los análisis de los datos más recientes del marcado (Bayliff y Rothschild, 1975 y IATTC, 1977), indican que no existe una fuerte tendencia en el atún aleta amarilla de desplazarse a aguas oceánicas a medida que envejecen. Sin embargo, esto solo puede verificarse al obtener más datos de recuperaciones de marcas y mediante una distribución más uniforme geográfica y temporal del esfuerzo de pesca.

Los estudios morfométricos mencionados anteriormente no indican que exista suficiente desplazamiento este-oeste que pueda resultar en la entremezcla de muchos peces entre el Pacífico oriental y central.

En el Pacífico occidental y central, se han realizado, hasta ahora, muy pocos experimentos de marcado, debido principalmente a que las artes palangreras no son adecuadas (el método principal de pesca de aleta amarilla en esta región) para realizar el marcado. Se han realizado cruceros experimentales de marcado, aprovechando la oportunidad de la pesca atunera con liña en los bancos del Pacífico occidental tropical. Sin embargo, los peces marcados se recapturaron cerca a los sitios de liberación y todos durante el año después de su liberación (Kikawa, 1971). Como indicaron Schaefer *et al.*, (1961) los atunes marcados cerca de los bancos pesqueros, se dispersan muy lentamente. Así que los experimentos de marcado no parecen ser adecuados para descubrir el grado de desplazamiento. Sin embargo, los datos inéditos del Tohoku Regional Fisheries Research Laboratory indicaron que un aleta amarilla marcado a los 9°56'N,

137°30'E fue recapturado a los 32°57'N, 136°40'E, y los datos inéditos del Far Seas Fisheries Research Laboratory que un aleta amarilla marcado a los 26°25'S, 154°15'E fue recapturado a los 36°26'S, 150°13'E. Estos desplazamientos tan distantes apoyan parcialmente la hipótesis de los desplazamientos de aleta amarilla a lo largo de las Corrientes de Kuroshio y de la Australiana del Este (Figura 26), según lo indica la distribución de los índices de captura palangreros.

Desplazamiento del aleta amarilla en el Pacífico occidental conjeturado según la distribución de los atunes y peces espada contaminados con radioactividad

El gobierno japonés realizó varias investigaciones, incluso algunas sobre atunes y peces espada para examinar la magnitud de la contaminación ambiental de los experimentos nucleares realizados por los EEUU desde el 1 de marzo al 5 de mayo de 1954, en el atolón Bikini (Fisheries Agency of Japan, 1955). Los análisis de la distribución de los atunes y peces espada contaminados, junto con el conocimiento de su distribución general, parece justificar el uso de dichos datos, al menos, para un estudio cualitativo de los movimientos del atún aleta amarilla (Fisheries Agency of Japan, 1955; Suda, 1956). La 3 Tabla, obtenida según un estudio del Fisheries Agency of Japan (1955), indica el porcentaje de los peces contaminados y la cantidad examinada de peces por especie, en las principales corrientes oceánicas. Esta tabla indica que:

- 1) no se encontraron casi ejemplares contaminados de marlín rayado (*Tetrapturus audax*) o albacora (*Thunnus alalunga*) en el hemisferio meridional; se supone que cada una de estas especies pertenece a diferentes subpoblaciones a las de sus contrapartes del hemisferio norte (Ueyanagi, 1966). Ninguna de estas especies gasta una parte importante de su tiempo en la Corriente Ecuatorial del Norte (Figura 26), donde se encuentra el atolón Bikini.
- 2) Por otra parte, los ejemplares contaminados de aleta amarilla, marlín azul (*Makaira nigricans*) y pez vela (*Istiophorus platypterus*), que no parecen confinados a las corrientes ecuatoriales, aparecen en grandes cantidades sobre extensas zonas.

Además, la composición de talla de los atunes aleta amarilla contaminados (formada por peces de más de 110 cm) que se encuentran en toda la Contra-corriente Ecuatorial del Norte y la Ecuatorial, es aproximadamente igual a la de la captura en esa zona de las dos corrientes (entre los 150°E-170°E) que rodean el atolón Bikini (Figura 24). Estos hechos indican que la contaminación del aleta amarilla ocurrió en una zona relativamente limitada del trópico.

En los informes anteriores sobre este sujeto, al combinar los datos de todas las especies se presentaron los detalles sobre la aparición de peces contaminados. Escogimos para nuestro estudio los datos del atún aleta amarilla muestreado en los mercados pesqueros de Tokio, Misaki y Yaizu

(puertos principales de desembarque de las embarcaciones palangreras). Desafortunadamente, el muestreo fue realizado solo en 1954 y se limitó en su mayoría al Pacífico occidental. Estos datos indican que el aleta amarilla contaminado aparece en casi todo el Pacífico occidental (Figura 25), lo que indica una mezcla considerable de aleta amarilla en esta zona.

Por lo consiguiente, se puede razonar que la inclinación longitudinal en los datos de longitud de la pesquería palangrera del Pacífico occidental, refleja desplazamientos específicos de talla del aleta amarilla desde zonas costeras a zonas oceánicas. Sin embargo, esta hipótesis sigue siendo indeterminada y se necesita más evidencia para probarla.

Al considerar todos los datos obtenidos, puede decirse que el aleta amarilla se desplaza probablemente en mayor escala que solo unos pocos cientos de millas, especialmente en una dirección este-oeste, como fue estimado por Royce (1964). Sin embargo, el grado de desplazamiento no parece que sea suficiente para permitir una mezcla considerable entre los peces del Pacífico oriental y central, como tampoco probablemente mucha entre el Pacífico occidental y central.

CONCLUSIONES

Ninguno de los datos empleados en este estudio (que abarca el Pacífico al este de los 130°E) indica claramente que existe una discontinuidad marcada en la población del aleta amarilla del Pacífico, pero los datos parecen confirmar el concepto de existencias "semiindependientes" con alguna mezcla conforme fue propuesto por Kamimura y Honma (1963), y Royce (1964). Además, debe indicarse que las tres existencias mencionadas están formadas posiblemente, a su vez, de subpoblaciones que no pueden ser discriminadas por tipos indirectos de datos obtenidos por las pescas como se emplean en este estudio. Si existen tales subpoblaciones se indica que aún el estudio verdaderamente genético de la captura no establecería su límite espacio-temporal.

La homogeneidad del aleta amarilla que habita aproximadamente la región entre los 120°E y los 180° se indica por tendencias a largo plazo de los índices de captura en las zonas principales de la pesca palangrera y la aparición de peces contaminados por radioactividad sobre extensas zonas del Pacífico occidental. Además de estas observaciones, los estudios de la distribución de larvas y de la madurez sexual presentan funciones de desove bastante diferentes en las zonas al oeste de los 180°. Así que al tomar en consideración el grado relativamente limitado de desplazamiento de esta especie, se considera que el aleta amarilla del Pacífico occidental entre los 120°E y 170°W pertenece a una existencia individual y que probablemente está siendo explotado en su totalidad por la pesca palangrera.

Además, la idea de una existencia independiente de aleta amarilla en el ARCAA del Pacífico oriental se considera como una suposición razonable a juzgar por la distribución de las larvas, la distribución de las proporciones

de captura y los desplazamientos de los peces marcados. La CIAT ha estimado que la producción de aleta amarilla en el ARCAA se encuentra cerca a su máximo con los métodos actuales de explotación.

Aunque existe poca evidencia para indicar positivamente la presencia de una existencia en el Pacífico central, los autores suponen tentativamente que el aleta amarilla de esta zona es una existencia diferente a la occidental u oriental. Como el aleta amarilla que se captura en el Pacífico central es comúnmente bastante grande, la producción del Pacífico central podría probablemente aumentarse, al reducir el promedio de la edad en la captura y al aumentar la mortalidad total por pesca.

APPENDIX 1

Length-frequency data from the Pacific Ocean longline fishery, 10°N-25°N. Catches are shown by 2-cm length intervals (midpoint given) for yellowfin caught between latitudes 10°N and 25°N by Japanese longliners during 1966 to 1972. Data are given by quarter for each year, stratified into area blocks of 10° by 15°, extending from the west coast of the Americas to longitude 130°E. The longitudes shown in the tables pertain to the left edge of a block when west of 180° or to the right edge when east of 180°. The area from the west coast of the Americas to 110°W is given by <110W. Frequencies are truncated at 58 cm and 158 cm.

ANEXO 1

Datos frecuencia-talla de la pesca palangrera en el Océano Pacífico, de los 10°N-25°N. Las capturas se presentan por intervalos de talla de 2 cm (se da el punto medio) para el aleta amarilla capturado por palangreros japoneses entre las latitudes de los 10°N y 25°N, en los años de 1966 a 1972. Los datos se dan por trimestre en cada año y se estratifican por bloques zonales de 10° por 15°, extendiéndose desde la costa occidental de las Américas hasta la longitud de los 130°E. Las longitudes indicadas en las tablas corresponden al margen izquierdo del bloque, cuando se encuentran al oeste de los 180° o al margen derecho cuando se encuentran al este de los 180°. La zona de la costa occidental de las Américas hasta los 110°W se indica mediante <110W. Se suprimen las frecuencias a los 58 cm y 158 cm.

APPENDIX 2

Length-frequency data from the Pacific Ocean longline fishery, 5°S to 10°N. These tables are like those of Appendix 1, except that the latitudes are from 5°S to 10°N.

ANEXO 2

Datos frecuencia talla de la pesca palangrera en el Océano Pacífico, de los 5°S a los 10°N. Estas tablas son semejantes a las del Anexo 1, excepto las latitudes que van desde los 5°S a los 10°N.

APPENDIX 3

Length-frequency data from the Pacific Ocean longline fishery, 5°S to 20°S. These tables are like those of Appendix 1, except the latitudes are from 5°S to 20°S.

ANEXO 3

Datos frecuencia-talla de la pesca palangrera en el Océano Pacífico. Estas tablas son semejantes a las del Anexo 1, excepto las latitudes que van desde los 5°S hasta los 20°S.

APPENDIX 4

Length-frequency data from the Pacific Ocean purse-seine fishery, inside the IATTC Yellowfin Regulatory Area (CYRA). Catches are shown by 2-cm length intervals (midpoint given) for yellowfin caught inside the CYRA by purse seiners during 1966 to 1972. Data are given by quarter for each year, and stratified by area as shown in Figure 20. Frequencies are truncated at 48 cm and 152 cm.

ANEXO 4

Datos frecuencia-talla de la pesca con cerco en el Océano Pacífico, en el Área Reglamentaria de la CIAT de Atún Aleta Amarilla (ARCAA). Las capturas se presentan por intervalos de talla de 2 cm (se da el punto medio) para el aleta amarilla capturado por cerqueros en el ARCAA desde 1966 a 1972. Los datos se dan por trimestre en cada año y se estratifican por zonas como se indica en la Figura 20. Se suprimen las frecuencias a los 48 cm y 152 cm.

APPENDIX 5

Length-frequency data from the Pacific Ocean purse-seine fishery, outside the IATTC Yellowfin Regulatory Area (CYRA) but east of 150°W. These tables are like those of Appendix 4, except that they cover 1969 to 1974, and are truncated at 54 cm and 160 cm.

ANEXO 5

Datos frecuencia-talla de la pesca con cerco en el Océano Pacífico fuera del Área Reglamentaria de la Comisión de Atún Aleta Amarilla (ARCAA), pero al este de los 150°W. Estas tablas son semejantes a las del Anexo 4, excepto que abarcan los años de 1969 a 1974 y se suprimen las frecuencias a los 54 cm y 160 cm.
